ASSOCIATION FOR COMPUTING MACHINERY
SPECIAL INTEREST GROUP ON AUTOMATA AND COMPUTABILITY THEORY
SPECIAL INTEREST GROUP ON PROGRAMMING LANGUAGES
AUTOMATIC DISCOVERY OF LINEAR RESTRANTS AMONG VARIABLES OF A PROGRAM

Patrick Cousot* and Nicolas Halbwachs**
Laboratoire d'Informatique, U.S.M.G., B.P. 53
38041 Grenoble cédex, France

1. INTRODUCTION

The model of abstract interpretation of programs developed by Cousot [1976], Cousot [1977] is applied to the static determination of linear equality or inequality relations among variables of programs.

For example, consider the following sorting procedure (Knuth [1973], p. 107):

```
procedure BUBBLESORT(integer value N; integer array[1:N] K);
begin
  B := N;
  (1) while B > 1 do
  (2)   J := 1; T := 0;
  (3)   while J < B-1 do
  (4)     if K[J] > K[J+1] then
  (5)       EXCHANGE(J, J+1); { no side effects on N, B, J, T}
  (6)     T := T + 1;
  (7)     J := J + 1;
  (8) end;
  (9) if T = 0 then return;
  (10) B := T;
  (11) end;
```

Without user provided inductive assertions nor human interaction we have automatically determined (in 1.502 seconds of C.P.U. time) that the following restraints must hold among the variables of the above procedure:

```
(1)  B = N
(2)  1 ≤ B ≤ N
(3)  1 ≤ B ≤ N, J = 1, T = 0
(4), (5), (6)  B ≥ N, T ≥ 0, T + 1 ≤ J ≥ 0
(7)  B ≥ N, J ≥ 1, J + 1 ≤ K ≤ N
(8)  B ≥ N, J ≥ 1, J + 1 ≥ K ≥ N
(9)  B ≥ N, J ≥ 1, J + 1 ≥ K ≥ N
(10), (11) B ≥ N, J ≥ 1, J + 1 ≥ K ≥ N
(12) J < N, T ≥ 0, T + 1 ≤ J, B = T
(13) B ≥ N, B ≥ 1
```

A certain number of classical data flow analysis techniques are included in or generalized by the determination of linear inequality relations among program variables. For example constant propagation can be understood as the discovery of very simple linear equality relations among variables (such as X = Y = 1). Moreover the resolution of the more general problem of determining linear equality relations among variables allows the discovery of symbolic constants (such as X=N, Y=5*N+1). The same way, common subexpressions can be recognized which are not formally identical but are semantically equivalent because of the relationships among variables. Also the loop invariant computations as well as loop induction variables (modified inside the loop by the same loop invariant quantity) can be determined on a basis which is not purely syntactical. The problem of discovering linear equality relations is in fact a particular case of the one of discovering linear inequality relations among the program variables. The main use of these inequality relationships is to determine at compile time whether the value of an expression is within a specified numeric or symbolic subrange of the integers or reals. This includes compile time overflow, integer subrange and array bound checking. In contrast to Suzuki-Ishihara [1977] we do not simply try to verify the legality assertions (such as verifying that array subsrcripts are within the declared range) but instead we try to discover the assertions (of linear type) that can be deduced from the semantics of the program. The advantage is that we can oten discover relations which are never stated explicitly in the program. For example, we can discover that an integer variable lies in a subrange of its declared range or that two references A[I] and A[J] to two elements of the same array refer to different storage locations (since e.g. I ≥ J + 1) or that some piece of code is dead.

The problem of determining equality relationships between a linear combination of the variables of the program and a constant was solved by Kerr [1976]. His approach was based on Wegbreit [1975] algorithm which requires that the properties to be discovered form a lattice every strictly increasing chain of which is of finite length. This assumption is not valid when considering inequality relationships (because of chains such as (x = 1), (1 ≤ x ≤ 2), ... , (1 ≤ x ≤ n), ...).

This work was supported by C.N.R.S. under grant ATP-Informatique D3119.
The model of Cousot [1977] is general enough to cope with this problem and we briefly recall it in section 2 as formulated in Cousot [1976]. In section 3 we study formal representations for the particular type of assertions that we consider. In section 4 we describe the linear restraints transformer corresponding to elementary instructions of the language. The algorithm performing the global analysis of programs is presented in section 5 by means of simple examples. Section 6 gives more convincing examples and Section 7 discusses the experimental implementation that has been realized.

2. APPROXIMATE ANALYSIS OF PROGRAM PROPERTIES, Cousot [1976].

For purposes of exposition, a sequential program will be represented by a connected finite flowchart with one entry node and assignment, test, join and exit nodes. The evaluations of the right-hand side of an assignment and of the boolean expression in a test node are assumed to not affect the values of any variables. Thus all side-effect phenomena must be modeled as assignment statements. The junction nodes contain no computations and represent the merge of program execution paths.

The analysis of a program consists in attaching to an assertion \( P_i(V_1, \ldots, V_n) \) to each arc \( i \) of the program. These predicates on the variables \( V_1, \ldots, V_n \) are not necessarily of the most general form but instead are modeled to design a specific aspect of the semantic properties of the program.

The assertion on the entry arc to the program represents what is known about the variables at the start of execution. For each other type of program node a transformation specifies the assertion associated with the output of the node in terms of the assertions on the input arcs to the node and where relevant the content of the node. Hence we have established a system of equations between the local assertions which can be solved by successive approximations (Cousot [1977]). Starting from no information on each arc, this resolution consists in propagating the entry assertion down the program graph by application of the transformation described for each type of node until stabilization. All possible paths are followed pseudo-parallelly with synchronization on junction nodes.

It is assumed that each cycle in the program graph contains a specially marked junction node which is called a loop junction node. In order to ensure stabilization the transformation for a loop junction node will be an approximation of the transformation for ordinary junction nodes. More precisely let \( P_{ij}, \ldots, P_{in} \) be the assertions associated with the input arcs of a junction node at step \( j \). Let \( Q_0 \) be the assertion associated with the output arc \( j \) of this node. Then \( Q_0 = \{ P_{i1}, \ldots, P_{in} \} \). For a loop junction node we have \( Q_0 = \{ \delta P_{i1}, \ldots, P_{in} \} \) where the widening operation \( \delta \) is performed at step \( j \) such that \( Q(V, P_{i1} \land \ldots \land Q_{in} \land P) \) for any chain \( \langle P_0 \Rightarrow P_1 \Rightarrow \ldots \Rightarrow P_n \Rightarrow \ldots \rangle \) the chain \( Q_{i0} \Rightarrow P_{i0} \), \( Q_{i0} = Q(V, P_{i1} \land \ldots \land Q_{in} \land P_{in}) \), \( Q_{i0} = \{ \delta P_{i1}, \ldots, P_{in} \} \) is not an infinite strictly increasing chain.

In the examples we shall use the algorithm described loosely above and in more detail in Cousot [1976].

3. FORMAL REPRESENTATIONS OF LINEAR RESTRAINTS AMONG VARIABLES OF A PROGRAM.

3.1. Linear system of a convex polyhedron.

Let \( \mathbf{x}, \mathbf{y}, \ldots, \mathbf{z} \) be the variables of the program. For simplicity we assume that the values of the variables belong to the set \( \mathbb{R} \) of reals. The set of solutions to a system of linear equations

\[
\begin{align*}
\mathbf{a}^i_1 \cdot \mathbf{x} & = \mathbf{b}^i_1, \\
\vdots & \quad \vdots \\
\mathbf{a}^i_m \cdot \mathbf{x} & = \mathbf{b}^i_m
\end{align*}
\]

where \( \mathbf{a}^i = (a^i_1, \ldots, a^i_m) \) and \( \mathbf{b}^i = (b^i_1, \ldots, b^i_m) \), is such solutions exist, is a linear variety of \( \mathbb{R}^m \). A linear variety of dimension \( n+1 \) in an hyperplane.

The set of solutions to a linear inequality

\[
\mathbf{a}^i_1 \cdot \mathbf{x} \leq \mathbf{b}^i
\]

is a closed half-space of \( \mathbb{R}^m \). For simplicity, strict inequalities are not considered. By linear restraints we mean either an equality or a linear inequality. In the formal reasoning we often consider that an equation can be viewed as two opposite inequalities.

A subset \( \mathcal{C} \) of \( \mathbb{R}^m \) is said to be convex if and only if \( \forall \mathbf{x}, \mathbf{y} \in \mathcal{C}, \lambda \mathbf{x} + (1-\lambda) \mathbf{y} \in \mathcal{C} \). For example linear varieties and half-spaces are convex.

The intersection of two convex sets is convex, but the union of two convex sets is not necessarily convex.

The set of solutions to a finite system of linear inequalities can be interpreted geometrically as the closed convex polyhedron of \( \mathbb{R}^m \) defined by the intersection of the closed halfspaces corresponding to each inequality.

3.2. The frame of a convex polyhedron, Weyl [1950], Kleene [1959], Church [1953].

Let \( V_1, \ldots, V_n \) be vectors in \( \mathbb{R}^m \). A vector of the form \( \sum_{i=1}^n \lambda_i V_i \) where each \( \lambda_i \in \mathbb{R} \) is called a linear combination of the \( V_i \). The set of all linear combinations of the \( V_i \) is the linear variety generated by the \( V_i \). A base of a linear variety \( L \) is a minimal set of vectors generating \( L \).

A vector of the form \( \sum_{i=1}^n \lambda_i V_i \) where each \( \lambda_i \in \mathbb{R}^m \) is called a convex combination of the \( V_i \). The set of all convex combinations of the \( V_i \) is the convex hull of the \( V_i \).

A vertex of a polyhedron \( P \) is a point \( v \) of \( P \) which is not a convex combination of other points of \( P \). The convex hull of \( P \) is the set of all convex combinations of \( P \).

A ray of a polyhedron \( P \) is a vector \( r \) such that there exists a half-line parallel to \( r \) and entirely included in \( P \) : \( \{x + r \mid x \in \mathbb{R}, x \cdot r = r \} \). Two rays \( r \) and \( r' \) are equal if and only if \( \{x + r' \mid x \in \mathbb{R} \} \). A ray of a polyhedron \( P \) is called an extreme ray if and only if it is not a positive combination of other rays \( r, \ldots, r_q \) of \( P \).

A vector \( v \) of \( \mathbb{R}^m \) is a vertex of \( \mathcal{C} \) if and only if \( \{x \in \mathbb{R}^m \mid x \cdot v = 0 \} \) is not a convex combination of other vectors \( u_1, \ldots, u_q \). A vector \( v \) of \( \mathbb{R}^m \) is an extreme vector of \( \mathcal{C} \) if and only if \( \{x \in \mathbb{R}^m \mid x \cdot v = 0 \} \) is not a convex combination of other vectors \( u_1, \ldots, u_q \). Intuitively, a ray (extreme ray) of a polyhedron is a point (vertex) translated to infinity.
A line of a polyhedron \( P \) is a vector \( d \) such that both \( d \) and \(-d\) are rays of \( P \): \((x \in \mathbb{R}, x+kd \in P)\). A polyhedron which contains at least one line is called a cylinder. The linear variety generated by all the lines of a cylinder is the greatest linear variety included in the cylinder. A polyhedron that contains no line has only a finite number of vertices and of extreme rays.

A bounded polyhedron has neither lines nor rays. Each point of a bounded polyhedron is a convex combination of the vertices of the polyhedron so that a bounded polyhedron is the convex-hull of its vertices.

Each point \( x \) of a polyhedron \( P \) which is not a cylinder can be expressed as the sum of a convex combination of the vertices \( \{a_1, \ldots, a_p\} \) of \( P \) and of a positive combination of the extreme rays \( \{r_1, \ldots, r_q\} \) of \( P \):

\[
\begin{align*}
x &= \sum_{j=1}^{q} \lambda_j r_j + \sum_{i=1}^{p} \mu_i a_i \\
\text{and } x &= \sum_{j=1}^{q} \lambda^0_j r_j^0 + \sum_{i=1}^{p} \mu^0_i a_i^0,
\end{align*}
\]

Let \( L \) be the greatest linear variety included in a cylinder \( P \). Let \( L \) be a linear variety orthogonal to \( L \). Then the intersection of \( L \) with \( P \) is a convex polyhedron which contains no line and which is called a section of \( P \) or a linear combination of the vectors of a base of the greatest linear variety included in \( P \).

By means of the vertices and rays or a cylinder will be the vertices and rays or a section of that cylinder.

A closed convex polyhedron \( P \) can be characterized by three sets \( S = \{a_1, \ldots, a_p\}, R = \{r_1, \ldots, r_q\}, D = \{d_1, \ldots, d_r\} \) of vectors of \( \mathbb{R}^n \) called the frame of the polyhedron as follows:

\[
(x \in P) \iff \left\{ \sum_{i=1}^{p} \mu_i a_i + \sum_{j=1}^{q} \lambda_j r_j + \sum_{k=1}^{r} \nu_k d_k \mid \mu_i, \lambda_j, \nu_k \leq 0 \right\}.
\]

We have two equivalent representations of a closed convex polyhedron either as the set of solutions of its system of linear restraints or as the convex hull of its frame. Example: The polyhedron derived by the following system of restraints:

\[
\begin{align*}
\sum_{j=1}^{q} \lambda_j x_j &= 1, \\
x^{1} &\geq 2, x^{2} \geq 2, x^{1} x^{2} &\geq 5,
\end{align*}
\]

is spanned by the following frame (see the diagram):

vertices: \( a_1 = \left( e_{1} \right), a_2 = \left( e_{2} \right), a_3 = \left( e_{3} \right) \)

extreme rays: \( r_1 = \left( e_{1} \right), r_2 = \left( e_{2} \right), r_3 = \left( e_{3} \right) \)

no line.

3.3. Conversions between the representations of a polyhedron by a system of linear restraints and by a frame.

Some operations that we have to perform on closed convex polyhedra are easy when these polyhedra are represented by systems of linear restraints while others are more simple when the frame representation is used. Hence we must be able to make conversions from one representation to the other.

3.3.1. Conversion from the frame to the linear restraints representation.

This conversion consists in finding a system of restraints for the convex-hull of the elements (points, rays, lines) of a frame. This conversion is followed by a simplification of the system of restraints.

3.3.1.1. Convex-hull of a finite frame.

Let \( S = \{a_1, \ldots, a_p\}, R = \{r_1, \ldots, r_q\}, D = \{d_1, \ldots, d_r\} \) be the frame of a non-empty polyhedron (so that \( S \neq \emptyset \)). The points \( x \) of this polyhedron are characterized by the existence of \( \lambda_1, \ldots, \lambda_p, \mu_1, \ldots, \mu_q, \nu_1, \ldots, \nu_r \) such that:

- \( \Sigma_{i=1}^{p} \lambda_i = 1 \)
- \( \Sigma_{j=1}^{q} \mu_j = 1 \)
- \( x = \Sigma_{k=1}^{r} \nu_k d_k \)
- \( \mu_j \leq 1 \)
- \( \nu_k \leq 1 \)

Before looking at the problem of conversion between these representations we need some definitions.

A face of a polyhedron \( P \) is a convex polyhedron \( F \cap P \) such that if a point \( x \) lies in \( F \) then each segment included in \( P \) and containing \( x \) is included in \( F \): \( x \in F, p \in F, \lambda x \in [0,1] \) and \( x = \lambda p + (1-\lambda) q \Rightarrow \lambda \in F \) and \( q \in F \).
Hence this polyhedron is characterized by a system of linear restraints in \( \mathbb{R}^{n+2+p+6} \) upon the variables \( x_1 (1=1..n), \lambda_j (1=1..\delta), \mu_j (1=1..\delta), \psi_k (1=1..\delta). \) Eliminating the \( \lambda, \mu, \psi \) we get a system of linear inequalities in \( \mathbb{R}^{n+2+p} \). This transformation can also be done by the projection operation used in Kuhn[1956].

Let us represent the system of m inequalities by \( A \leq B \) where \( A \) is a \( m \times n \) real matrix and \( B \) a \( m \times 1 \) vector. In order to eliminate the variable \( x_C \) we project according to the column \( C \) upon \( A \leq B \) in order to get a simplified projected system defined as follows:

- For each row \( A^1 \) such that \( A^1 \leq 0 \), the restraints \( A^1 \leq B \) is part of the projected system.
- For each two rows \( A^{11} \) and \( A^{12} \) such that \( A^{11} \leq A^{12} < 0 \), the restraints \( [A^{11}] \leq [A^{12}] \leq [A^{12}] \leq B \) is part of the projected system.

The projected system contains only zeros in the column \( C \) hence it is independent of \( x_C \).

Example: Eliminating \( \lambda \) in the system

\[
\begin{align*}
-\lambda & \leq 0 \\
\lambda & \geq 1 \\
-x_1 & \leq 0 \\
x_1 - x_2 & \leq 0 \\
-2x_1 & \leq 0 \\
x_1 - x_2 & \leq 2 \\
x_1 + x_2 & \leq 2
\end{align*}
\]

we get

\[
\begin{align*}
-x_3 & \leq 0 \\
x_1 - x_2 & \leq 2
\end{align*}
\]

End of example.

The convex-hull of the frame \( S, R, D \) is computed by successive approximations \( P_1, P_2, \ldots, P_{n+p+6} \) as follows:

- \( P_1 \) is the point \( s_1 \) so that the corresponding system of restraints is \( (x_1 s_1) \). Then for each \( x \neq 2.3.4 \), \( P_i \) is the convex-hull of \( P_{i-1} \) and the point \( x_i \). Therefore \( \{x_i P_i\} \) if and only if \( \{x_i P_{i-1}\} \).

\[ \lambda \{[0,1] : x \leq \lambda \} \] is a convex-hull of the system of restraints describing \( P_{i-1} \). It can be shown that this is equivalent to \( \{x \leq [0,1] \} \) as \( x \) is the convex-hull of the system of restraints which are not equals. Let \( \lambda \leq 0 \) be the quasi-ordering defined by \( \{C \leq C' \} \Rightarrow \{x \leq s \} \Rightarrow \{x \leq s \} \).

\( C \leq C' \) means that \( C \) is saturated by any vertex or ray saturating \( C' \). \( C \leq C' \) but not \( C \leq C' \) then \( C \) is irrelevant. \( C \leq C' \) and \( C \leq C' \) then one and only one of the inequalities is irrelevant so that one of them can be excluded. Applying these results to a system of restraints we obtain a minimal system of restraints (with no irrelevant inequality) corresponding to the same polyhedron.

3.3.1.2. Simplification of a system of linear inequalities.

It is often the case that projections leads to projected systems of restraints containing a great number of irrelevant restraints which can be eliminated without changing the polyhedron represented by the system of restraints. For the sake of efficiency these irrelevant restraints must be excluded. Knowing a frame of the polyhedron, the corresponding system of linear inequalities can be simplified according to the following remarks due to Lanery[1966]:

- An inequality which is never saturated by a vertex of the frame is irrelevant.
- An inequality which is saturated by all vertices and all rays of the frame represents an equality. All the equalities are found in that way.
- Let \( C_1 : (a_1 \leq b_1) \) and \( C_2 : (a_2 \leq b_2) \) be two inequalities of the system of restraints which are not equations. Let \( \lambda \geq 0 \) be the quasi-ordering defined by \( \{C_1 \leq C_2 \} \Rightarrow \{\lambda x \leq \lambda s \} \Rightarrow \{a \leq s \} \).

\( C \leq C' \) means that \( C \) is saturated by any vertex or ray saturating \( C' \). \( C \leq C' \) but not \( C \leq C' \) then \( C \) is irrelevant. \( C \leq C' \) and \( C \leq C' \) then one and only one of the inequalities is irrelevant so that one of them can be excluded. Applying these results to a system of restraints we obtain a minimal system of restraints (with no irrelevant inequality) corresponding to the same polyhedron.

3.4. Conversion from the linear restraints to the frame representation of the polyhedron.

Based on the pivot method of linear programming, numerous algorithms have been designed to find all vertices of a convex polyhedron (Balinski[1961], Lanery[1966], Manso-Nedome[1968], Mathies[1973], Ody-Prill[1977]). We shall give a brief description of Lanery's method which is general enough to find a frame (vertices, extreme rays, lines) of a convex polyhedron. We first recall some elements of linear programming (Simmonds[1973]).
3.4.1. Basic concepts of linear programming

A system of linear inequalities:
\[ \left\{ \begin{array}{l}
\Sigma_{j=1}^{n} \left( a_{1j} x_1 + \ldots + a_{mj} x_m \right) \\ i \leq 0, \quad j = 1 \ldots m
\end{array} \right. \]
can be written in the equivalent form:
\[ \left\{ \begin{array}{l}
\Sigma_{j=1}^{n} \left( g_{1j} y_1 - b_1, \ldots, g_{nj} y_n - b_n \right) \\ y_i \geq 0, \quad j = 1 \ldots m
\end{array} \right. \]
Hence a system of constraints can be written in standard form:
\[ AX = B, \quad X \geq 0 \]
where \( A \) is an \( (m \times n) \) matrix, \( B \) is an \( m \)-vector, and \( X \) is an \( n \)-vector. The variables \( x_i \) are the initial variables, the variables \( y_i \) are the slack variables.

A basic of the system (3.4.1.2) is a non singular \( n \times m \) submatrix \( A_i \) of \( A \). The system can be written in canonical form with respect to the basis \( A_i \):
\[ \begin{bmatrix} x_1 \ldots x_n \end{bmatrix} = \begin{bmatrix} A_i^{-1} x_i \end{bmatrix} + \begin{bmatrix} b \end{bmatrix} \]
\( i = 1, \ldots, m \). The variables \( x_i \) such that \( x_i \) is a basic variable is called basic if and only if \( (A_i^{-1} B) \geq 0 \). Two feasible bases \( A_i \) and \( A_j \) are said to be adjacent if and only if the cardinal of the set \( \{ i \} \) is equal to \( m-1 \). If two bases are adjacent, the classical pivot operation transforms the system written in canonical form with respect to \( A_i \) into an equivalent system in canonical form with respect to \( A_j \). The artificial basis method which is the initialization step of the simplex method transforms the system of constraints (3.4.1.3) into an equivalent system in canonical form (3.4.1.2) with respect to a feasible basis of (3.4.1.2) whenever such a basis exists.

3.4.2. Principles of Lanery's method.

The graph of the adjacency relation on the set \( \{ A_i \} \) of feasible bases containing all initial variables \( \{ \ell \} \) such that \( \ell \subseteq \{ i \} \) is connected. Hence given such a system, we can by successive pivoting operations and an exhaustive traversal technique find all feasible basis of a given system of constraints.

- If \( A_i \) is a feasible basis such that \( \ell \subseteq \{ i \} \) then the vector \( (A_i^{-1} B)^\ell \) corresponds to a vertex of the convex polyhedron defined by the system of constraints. To each vertex of a polyhedron containing no line corresponds at least one feasible basis. If two vertices are adjacent then there are two adjacent feasible bases corresponding to them.

- Let \( (AX = B, X \geq 0) \) be the canonical form of a system of constraints with respect to the feasible basis \( A_i \) containing all initial variables. Then Lanery shows that if column \( i \subseteq \{ \ell \} \) satisfies the condition:
\[ \begin{bmatrix} \ell \subseteq \{ i \} \end{bmatrix} \{ x_i \} \geq 0 \]
then \( x_i \) is a basic variable. The unique index \( i \subseteq \{ i \} \) such that \( x_i \) is basic is 1.

Thus Lanery shows that column \( i \subseteq \{ i \} \) corresponds to a line of the polyhedron.

Also if the basis \( A_i \) is such that each \( \ell \subseteq \{ i \} \) verifies the property (3.4.2.2), then the set \( \{ \ell \} \) is a basis of the greatest linear variety contained in the polyhedron.

3.4.3. Algorithm for finding the frame of a convex polyhedron.

Let \( A X = B \) be a system of \( m \) linear restrictions among the variables \( x \in \mathbb{R}^n \).

1. Build the standard form \( A = [\mathbf{0} | X = B] \), \( X \geq 0 \), where \( x \in \mathbb{R}^m \).
2. Apply the first step of the simplex method.

- If there is no feasible basis, the polyhedron is empty. Otherwise we get the system \( A X = B \), \( X \geq 0 \) in canonical form with respect to the feasible basis \( A_i \) with \( (B_i) \geq 0 \).
3. While there exists an initial variable staying out of the basis and satisfying (3.4.2.2) perform a pivoting which puts this variable in the basis by removing a slack variable from the basis.
4. We get a system \( A = [\mathbf{0} | X = B] \), \( X \geq 0 \) in canonical form with respect to the basis \( i \). Two subcases must be considered:
4.1. If all initial variables are in the basis (\( \ell \subseteq \{ i \} \), then the polyhedron contains no line and a vertex has been found. Then traverse exhaustively all feasible bases of the system and note at each step the vertex and the ray that is found. An efficient algorithm for this travel is given by Dyer-Proll(1971).
4.2. The initial variables \( x_1, \ldots, x_\ell \) possibly remaining out of the basis verify (3.4.2.2). So \( (d_1, \ldots, d_{\ell}) \) is a basis of the greatest linear variety contained in the polyhedron. The following system of restraints
\{(x_5 \in \mathbb{R}, \sum_{i=1}^{5} x_i = 0, x_i \geq 0, x_i \geq 0, 1 \leq k \leq 5) \}
 defines a new polyhedron \( P' \) which is a section of the initial polyhedron. Applying the algorithm to this new system of constraints case 4.1 is applicable since \( P' \) contains no lines so that the algorithm terminates.

Example: Let us compute a frame of the polyhedron \( P \) corresponding to the following system of constraints:
\[
\begin{align*}
- x_1 + x_2 - x_3 & \leq 0 \\
- x_1 & \leq -1 \\
- x_1 - x_2 + x_3 & \leq 0 \\
- x_2 + x_3 & \leq 3
\end{align*}
\]

1-Using the matrix notations for denoting systems of equations the standard form of [S1] is:
\[
\begin{array}{ccccccc}
  x^1 & x^2 & x^3 & x^4 & x^5 & x^6 & x^7 \\
-1 & 1 & -1 & 0 & 0 & 0 & 0 \\
-1 & -1 & 0 & 0 & 1 & 0 & 0 \\
0 & -1 & 1 & 0 & 0 & 0 & 0 \\
0 & 0 & -1 & 0 & 0 & 0 & 1
\end{array}
\]

The system [S2] is in canonical form with respect to the infeasible basis \( A_{\{1,2,5,6,7\}} \).

2-The artificial basis method supplies the system [S3] in canonical form with respect to the basis \( A_{\{1,7,4,6,5\}} \) which is feasible:
\[
\begin{array}{ccccccc}
  x^1 & x^2 & x^3 & x^4 & x^5 & x^6 & x^7 \\
0 & 1 & -1 & -1 & 0 & 0 & 0 \\
0 & 0 & 0 & -1 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 1 & 0 & 1 \\
0 & 0 & 0 & 0 & 0 & 0 & 1
\end{array}
\]

3-Then we put into the basis as many initial variables as we can, we got the basis \( A_{\{2,3,1,6,7\}} \):
\[
\begin{array}{ccccccc}
  x^1 & x^2 & x^3 & x^4 & x^5 & x^6 & x^7 \\
0 & 1 & -1 & 1 & 0 & 0 & 0 \\
1 & 0 & 0 & 0 & 0 & 0 & 1 \\
0 & 0 & 0 & 1 & -2 & 1 & 0 \\
0 & 0 & 0 & 0 & 1 & -1 & 1
\end{array}
\]

4-The initial variable \( x^2 \) remains out of the basis and cannot be put into the basis without getting \( x^2 \) out. The third column verifies [3.4.2.2]. Hence the vector \( = (0,1,1) \) is the only line of the polyhedron \( P \). Let us build the system of restraints of a section of \( P \).
\[
\begin{align*}
- x_1 + x_2 - x_3 & \leq 0 \\
- x_1 & \leq -1 \\
- x_1 - x_2 + x_3 & \leq 0 \\
- x_2 + x_3 & \leq 3
\end{align*}
\]

Applying (1) and (2) to [S5] we get the canonical form with respect to the feasible basis \( A_{\{2,3,1,6,7\}} \) which contains all initial variables. Thus we have found a first vertex of \( P' \) and we start the traversal of the graph of vertices:

\[
\begin{array}{cccccccc}
  x^1 & x^2 & x^3 & x^4 & x^5 & x^6 & x^7 \\
0 & 1 & 0 & -2 & -2 & 0 & 0 & 1 \\
0 & 0 & 1 & -1 & 0 & 0 & 0 & 1/2 \\
0 & 0 & 0 & 1 & -2 & 1 & 0 & 0 \\
0 & 0 & 0 & 0 & 1 & -1 & 0 & 1
\end{array}
\]

Basis: \( A_{\{1,3,5,7,6\}} \)
Vertex: \( s_1 = (1,1/2,1/2) \)
Column 5 satisfies [3.4.2.1]
Ray: \( r_1 = (1,1/2,1/2) \)
Adjacent feasible basis: \( A_{\{2,3,1,6,7\}} \) already found

\[
\begin{array}{cccccccc}
  x^1 & x^2 & x^3 & x^4 & x^5 & x^6 & x^7 \\
0 & 1 & 0 & 0 & 0 & 0 & 0 & 1/2 \\
0 & 0 & 1 & 0 & 0 & 0 & -2 & -1/2 \\
0 & 0 & 0 & 1 & -2 & 1 & 0 & 0 \\
0 & 0 & 0 & 0 & 1 & -1 & 1 & 2
\end{array}
\]

Basis: \( A_{\{1,2,5,6,7\}} \)
Vertex: \( s_2 = (1,1/2,1/2) \)
Column 5 satisfies [3.4.2.1]
Adjacent feasible bases: \( A_{\{2,3,1,6,7\}} \) already found

\[
\begin{array}{cccccccc}
  x^1 & x^2 & x^3 & x^4 & x^5 & x^6 & x^7 \\
0 & 1 & 0 & 0 & 0 & 0 & 1/2 & 3/2 \\
0 & 0 & 1 & 0 & 0 & 0 & -2 & 2/3 \\
0 & 0 & 0 & 1 & -2 & 1 & -1 & 2 \\
0 & 0 & 0 & 0 & 1 & -1 & 1 & 2
\end{array}
\]

Basis: \( A_{\{1,2,3,5,6\}} \)
Vertex: \( s_3 = (3,-3/2,3/2) \)
Column 6 satisfies [3.4.2.1]
Ray: \( r_2 = (1,0,0) \)
Adjacent feasible basis: \( A_{\{2,3,1,6,7\}} \) already found

All feasible bases that contain initial variables have been found, the algorithm terminates with the following frame for \( P' \):
\[
[S = \{(1/2,1/2), (1,1/2,1/2), (0,1,1)\}], \quad R = \{(1/2,1/2), (1,0,0)\}, \quad D = \{(0,1,1)\}\]
End of example.

3.4.4. Simplification of a frame

Lanary[1966] proposes a method for eliminating all irrelevant members of a frame when a system of restraints of the polyhedron is known. This method is the dual of the one given at paragraph 3.3.1.2. For simplifying a system of inequalities. Lanary's method is based on the following results:
- A vertex or a ray saturating no inequality is irrelevant.
- A ray saturating all restraints corresponds to a line.
- If \( a_1 \) and \( a_2 \) are two vertices or two rays (which are not lines) in the frame the quasi-ordering \( \leq \) is defined by:
  \[
  [a_1 \leq a_2] \iff \{\text{every inequality saturated by } a_1 \text{ is saturated by } a_2\}
  \]
  if \( a_1 \leq a_2 \) or \( [a_1 \leq a_2] \) imply that \( a_1 \) is irrelevant
  \[
  [a_1 \leq a_2] \text{ and } [a_2 \leq a_1] \text{ imply that one but only one of the two elements may be eliminated.}
  \]
3.5. On the use of two representations for assertions.

The search for the frame of a polyhedron as described above may become very expensive although many important optimizations are possible. The number of vertices of a polyhedron generated in $\mathbb{R}^n$ by m inequalities is known to be bounded only by functions increasing very quickly with m and n. Sato[1965], Klee[1966]. So the use of this method should be avoided except when applied to polyhedra which are thought to have very few vertices. However, the use of two representations is necessary for the following reasons:

- All polyhedra can only be defined on the frame representation, others like widening require the restraint representation.
- In order to define the inclusion relation between two polyhedra it is very useful to know both representations. Indeed, $P_1 \subseteq P_2$ if and only if each element of the frame of $P_1$ satisfies the restraint of $P_2$.
- It appears that it is difficult to simplify one representation without knowing the other one and neither can be used efficiently without simplifications. So we shall build at the same time and in a consistent way the systems of restraints and the bases of the polyhedra. Both representations will be simultaneously used to represent the assertions. Experience shows that this redundant representation is much less expensive than the frequent use of conversions.

4. TRANSFORMATION OF LINEAR ASSERTIONS BY ELEMENTARY LANGUAGE CONSTRUCTS.

Given the flowchart representation of programs we now give for each type of program node a transformation specifying the assertion associated with the output arcs of the node in terms of the assertions associated with the input arc(s) of the node and where relevant the content of this node. The conditions of Cousot[1977] guaranteeing the correctness of these transformations apply to the specific case analyzed here.

4.2. Assignment.

Let $\{A,B,S,R,D\}$ be the representation of the input assertion $P'$ corresponding to the polyhedron $AX$ and the frame of which is $S=\{a_i : i=1..d\}$, $R=\{r_j : j=1..p\}$, $D=\{d_k : k=1..q\}$. Then the representation of the output assertion $P''$ after the assignment $X^1_0=E(X)$ is given by

$$assign (P'', X^2_0=E(X)) = \{A',B',S',R',D'\}.$$ 

4.2.1 Assignment of a non-linear expression.

If the expression $E(X)$ is not linear it is assumed that any value of $R$ can be assigned to $X^1_0$. Hence after the assignment $X^1_0=E(X)$ nothing is known about the value of $X^2_0$. Therefore $X^2_0$ is eliminated from the system of restraints $AXB$ by a projection along the column $i_0$ (§3.3.1.1). For the frame representation this consists in adding the line $d$ such that $d_{i_0}=1$ and $d_j=0$ for every $j \neq i_0$ different from $i_0$ to the set of lines $D$. Then in general the representation $\{A',B',S',R',D'\}$ of $P''$ is not minimal and must be simplified (§3.3.1.2 and §3.4.4).

Example: Let $n=2$ and $P'$ be the input assertion represented by the system of restraints:

$$\begin{align*}
x_1 - x_2 & \geq -1 \\
x_2 & \geq 1 \\
x_1^2 + x_2^2 & \geq 5
\end{align*}$$

The frame representation is $S=\{(2,3),(4,1)\}$, $R=\{(1,1),(1,0)\}$, $D=\emptyset$. The geometrical interpretation is:

The output assertion $P''$ after the assignment $X_2=x_1x_2$ is $\{x_1=0, x_1x_2\}$, the frame of which is $S'=\{(4,1)\}$, $R'=\{(1,0)\}$, $D'=\{0,1\}$. That is:

$$\begin{align*}
x_1 & \geq 0 \\
x_1 & \leq 4 \\
x_2 & \geq 1 \\
x_2 & \leq 2.3 \\
x_1x_2 & \geq 0
\end{align*}$$

Simplifying we get $\{x_1\geq 2\}$, $S'=\{(1,1)\}$, $R'=\{(1,0)\}$. $D'=\{0,1\}$ that is:

$$\begin{align*}
x_1 & \geq 2 \\
x_1 & \leq 4 \\
x_2 & \geq 1 \\
x_2 & \leq 2.3
\end{align*}$$
The approximation is obviously very coarse since the substitution of $x_1 x_2$ for $x_2$ in the input system of constraints would lead to:

\[
\begin{align*}
  x_2 &\leq x_2^1(x_1)^2 \\
  x_2 &\geq x_1 \\
  x_2 &\geq 5x_2^1(x_1)^2
\end{align*}
\]

However the corresponding domain is not a polyhedron and this situation is hardly manageable.

Note however that the exact domain is covered by the approximate domain (Courset[27]). Also, a more precise analysis is feasible. For example, \{$x_2 \geq 0$, and $x_2 \leq 0$\} implies \{$x_1 x_2 \geq 0$\} of the assignment $x = y(1+2)$ implies that $x$ is greater than or equal to zero.

**End of example.**

### 4.2.2. Assignment of a linear expression

The assignment is of the form $X^c = \Sigma_{k=1}^n (a_z x^i + b)$ where $a_z$ is a $n$-row vector of integers or reals and $b$ is an integer or a real. The transformation constrains $a_z x^i + b$.

$\mathbb{R}^n$. The output assertion $P'$ is defined by the frame $(S', R', D')$ computed as follows:

- \( S' = \{s_1, \ldots, s_n\} \) where $s_{i}^{z}$ is defined by $y_{i}^{z}=a_{z,i}+b$ and $s_{i}^{z}=1$ where $i=1,\ldots,n$ and $1\neq i$.
- \( R' = \{r_{1}^{z}, \ldots, r_{n}^{z}\} \) where $r_{i}^{z}$ is the vector defined by $r_{i}^{z} = a_{z,i}$ and $r_{i}^{z} = 1$ for $i=1,\ldots,n$ and $1\neq i$.
- \( D' = \{d_{1}^{z}, \ldots, d_{n}^{z}\} \) where $d_{i}^{z}$ is the vector defined by $d_{i}^{z} = a_{z,i}$ and $d_{i}^{z} = 1$ for $i=1,\ldots,n$ and $1\neq i$.

The system of restraints corresponding to $P'$ can be obtained as the convex hull of the frame $(S', R', D')$. However, following Karr[76] this system of restraints can be computed directly.

#### 4.2.2.1. Invertible assignments

The assignment is of the form $X^c = \Sigma_{k=1}^n (a_z x^i) + b$ a $1\neq 0$. The fact that $1\neq 0$ allows us to carry over our knowledge of the previous value of $X^c$ to the new value of $X^c$. To see this, denote the values of the variables by $X$ before and by $X'$ after the invertible assignment statement. Then for $i=1,\ldots,n$ and $1\neq i$ we have $X^c = x^i$ whereas $X^c = a(x+b)$. Therefore $X=MX^{m+k}$ as defined by:

\[
X^c = \frac{(X^{c+1} - (aX^{c+1}) - b)/a_{1}}{a_{1}}
\]

Also \( A \leq B \) is equivalent to \( \{(\max x'_i \leq (B-A)X) \} \) which leads to the output system of restraints satisfied by $X'$.

#### 4.2.2.2. Non-invertible assignments

If $a_{1}=0$ then we cannot solve $X'$ in terms of $X$ so that some information is lost by the assignment. Hence $X^c$ is eliminated from the input restraints by a projection operation. The case is similar to the one of the assignment of a non-linear expression except that the restraint $X^c = ax+b$ is adjoined to the resulting system.

**Example:**

Let $P$ be the input assertion defined by:

\[
\begin{align*}
  x_2 &\geq 1 \\
  x_1 x_2 &\geq 5 \\
  x_1 - x_2 &\geq -1
\end{align*}
\]

The assignment $x_2 := x_1 + 1$ is not invertible. The elimination of $x_2$ in the input system of restraints leads to \(\{x_1 \geq 2\}\) so that the output system of restraints is:

\[
\begin{align*}
  x_2 &\geq x_2 - x_1 = 1 \\
  x_1 - x_2 &\geq -1
\end{align*}
\]

The assignment $x_2 := x_1^2 + 2$ is invertible so that $x_1 = x_1^2$ and $x_2 = 2x_1^2 + 2x_1 - 2$. Substituting in the input system of restraints we get the output system:

\[
\begin{align*}
  2x_1^2 - 2x_1^2 &\geq 3 \\
  2x_1^2 - x_1^2 &\geq 7 \\
  -2x_1^2 + 3x_1^2 &\geq -3
\end{align*}
\]

**End of example.**

### 4.3. Test Nodes

Let $P(A,B,S,R,D)$ be the assertion associated...
with the input arc to a decision node testing some boolean condition \( C \). Let \( P_t(A_t,B_t,C_t,D_t) \) and \( P_f(A_f,B_f,C_f,D_f) \) be the assertions associated respectively with the true and false exits of the test. Obviously \( P_t \equiv P \) and \( C_t \equiv C \) and \( P_f \equiv P \) and \( \neg C(C) \).

The condition \( C \) is said to be linear if and only if it is of the form \( ax \leq b \) or \( ax = b \) where \( a \) is an \( n \)-row-vector of integers or reals, \( X \) is the \( n \)-column-vector of program variables and \( b \) is an integer or a real.

### 4.3.1. Non-linear tests.

If \( C \) is not a linear condition we "ignore" the test by putting \( P_t = P = P_f \). This is certainly valid, but it may not be as much information as could be gathered. As for non linear assignments specific studies can be made of how best to handle test conditions which are not linear (for example \( \log(x) \) does \( \not\in \{\{a \mid a \geq 0\} \)\( \end{linenomath} \).

### 4.3.2. Linear equality tests.

When \( C \) is a linear condition let \( H \) be the hyperplane \( \{x \in \mathbb{R}^n \mid ax = b\} \).

If \( C \) is of the from \( ax = b \) then either \( P \) is included in \( H \) in which case \( P_t = P = P_f \) or \( P \) is not included in \( H \) in which case \( P_t \not\equiv P \) and \( P_f \not\equiv P \). Note that \( \{ax = b\} \) is approximated by \( \{ax \leq b\} \) and \( \{ax \geq b\} \), in general, a closed convex polyhedron.

The frame of \( PNH \) is found thanks to the following results:

1. 1- A vertex \( s \) of \( PNH \) lies on an edge of \( P \) according to one of the following alternatives:
   1.1- \( s \) is a vertex of \( P \) that belongs to \( H \),
   1.2- there are two adjacent vertices \( s_1 \) and \( s_2 \) of \( P \) such that \( s = s_1 + (1- \lambda)s_2 \) where \( \lambda = (b-a s_1)/(a s_2 - a s_1) \) belongs to \( [0,1] \).
   1.3- there are a vertex \( s_1 \) and a ray \( r_1 \) of \( P \) such that \( s_1 \) is adjacent to \( r_1 \) in \( P \) and \( s = s_1 + \mu r_1 \) where \( \mu = (b-a s_1)/a r_1 \) is positive.
   1.4- there are a vertex \( s_1 \) and a line \( l_1 \) of \( P \) such that \( s = s_1 + \mu l_1 \) where \( \mu = (b-a s_1)/a l_1 \).

2. Each extreme ray \( r \) of \( PNH \) is either
   2.1- an extreme ray of \( P \) that belongs to \( H \),
   2.2- or, a positive combination of two adjacent extreme rays \( r_1 \) and \( r_2 \) of \( P \) for \( r = \lambda r_1 + \mu r_2 \) where \( \mu = a r_1/a r_2 \) must be positive.
   2.3- or the sum of an extreme ray \( r_1 \) of \( P \) and a vector linearly dependent of a line \( l_1 \) of \( P \), that is \( r = r_1 + (\lambda a r_1/ a l_1) l_1 \).

3. Finally a vector \( d \) is a line of \( PNH \) if and only if there are two lines \( d_1 \) and \( d_2 \) in \( P \) such that \( d = d_1 - (a d_2)/a d_1 d_2 \).

### 4.3.3. Linear inequality tests

If \( C \) is of the form \( ax \leq b \) then \( P_t = (P \text{ and } ax \leq b) \)

whereas \( P_f = (P \text{ and } ax > b) \).

Note that the inequality is not strict since \( P_f \) must be a closed polyhedron and that we can write \( ax \leq b + 1 \) for integers.

As above, the determination of the frames of \( P_t \) and \( P_f \) makes use of a frame \( (S', R', D') \) of the intersection \( PNH \) of \( P \) with the hyperplane \( P_t = (ax \leq b) \).

The set \( S_t \) of vertices of \( P_t \) is \( \{ax \leq b \} \).

If \( S_t \) is empty then \( P_t \) is the empty polyhedron whereas \( P_f \) equals \( P \).

Otherwise \( S_t \) is not empty and \( T \) the set \( T \) of extreme rays of \( P_t \) is \( \{r \in R \mid r \not\leq 0 \} \cup \{r \in R \mid r \not\leq 0 \} \cup \{r \in R \mid r \not\leq 0 \} \cup \{r \in R \mid r \not\leq 0 \} \).

The set of lines \( D_t \) of \( P_t \) is \( D' \). A symmetric reasoning is used to determine a frame of \( P_f \).

The resulting frames \( \langle S_t, R_t, D_t \rangle \) and \( \langle S_f, R_f, D_f \rangle \) are not necessarily minimal and must be simplified.

**Example:** Let \( P \) be an input assertion defined by \( \{x \leq 1, x_1 + x_2 \leq 5, x_1 \geq 1\} \), \( S = \{(1,1), (2,1)\} \), \( R = \{(1,1), (2,1)\} \), \( D = \emptyset \).

Let \( P_t \) and \( P_f \) be the output assertions associated respectively with the true and false exits of a test on the condition \( x_1 + 2x_2 \leq 7 \) that is \( ax \leq b \) where \( a = (1,2) \), \( b = 8 \) and \( X \) is the \( 2 \)-column-vector \( (x_1, x_2) \).

Let \( H \) be the hyperplane defined by the equation \( x_1 + 2x_2 \leq 7 \). The geometrical interpretation is the following:

![Diagram](image.png)

In order to determine a frame of \( PNH \), it is necessary to know the adjacent elements of the frame of \( B \). For \( r = (1,0) \), \( r' = (0,1) \) are adjacent. The vertex \( s' \) of \( H \) corresponds to the case 4.3.2.1.3, that is \( s' = s_2 - (a_2 - a_1)/(a_1 - a_2) s_1 = (4,5) \).

The extreme ray \( r' \) of \( PNH \) corresponds to case 4.3.2.2.2 that is \( r' = r_1 - (a_1 - a_2)/a_1 r_2 = (2,1) \).

A frame of \( P_t \) is given by \( S_t = \{s_1, s_2, s_3\} \), \( R_t = \{r_1, r'\} \), \( D_t = \emptyset \).

A frame of \( P_f \) is given by \( S_f = \{s'\} \),

92
\[ R_p = (r_z, r^*). \quad D_p = \emptyset. \]

End of example.

### 4.4. Simple junction nodes

Simple junction nodes correspond for example to the merge of the "then" and "else" paths in a conditional statement. More generally let \( P_1, P_2, \ldots, P_p \) be the assertions associated with the input arcs to the simple junction node and \( P \) the output assertion:

![Simple junction node diagram]

Then the output assertion \( \text{OR}^p \{P_i\} \) does not necessarily correspond to a convex polyhedron so that it must be approximated by the convex-hull of \( P_1, \ldots, P_p \) which is the least polyhedron containing \( P_1, \ldots, P_p \).

Since the convex-hull operation is associative we can assume without loss of generality that there are two input arcs (p=2). Given \( P_1(A_1, B_1, S_1, D_1) \) and \( P_2(A_2, B_2, S_2, R_2, D_2) \) the frame of \( \mathcal{P} = \text{convex-hull}(P_1, P_2) \) is \( S = S_1 \cup S_2 \), \( R = R_1 \cup R_2 \) and \( D = D_1 \cup D_2 \). The system of constraints \( A \times B \) describing \( \mathcal{P} \) is obtained by the convex-hull of the frame \( (S, R, D) \) which can be computed by successive approximations (§ 3.3.1.1). As soon as the system of constraints \( (A \times B) \) of \( \mathcal{P} \) is known the frame \( (S, R, D) \) of \( \mathcal{P} \) can be simplified (§ 3.4).

Notice that \( \text{convex-hull}(P_1, P_2) \) cannot be computed directly from the systems of constraints \( A_1 \times B_1 \) and \( A_2 \times B_2 \). In order to avoid a costly conversion (§ 3.4) the redundant frame representation has been kept along with the constraints representation. For the output assertion \( \mathcal{P} \) the conversion from frame \( (S, R, D) \) to constraints \( A \times B \) representation is less expensive (§ 3.3). Since the system of constraints of \( P_1 \) (or \( P_2 \)) is known this conversion is optimized as follows:

\[
\text{convex-hull}(A \times B) = \text{convex-hull}(A \times B_1) \cup \text{convex-hull}(A \times B_2)
\]

so that starting from \( A \times B \), we can successively incorporate in the convex-hull the elements of the frame of \( P_1 \).

**Example:**

\[ P_1 = \{(x_1 \geq 0, x_2 \geq 0, x_1 + x_2 \leq 1), S_1 = \{(0, 0), (1, 0), (0, 1), R_1 = \emptyset, D_1 = \emptyset\} \]

\[ P_2 = \{(x_1 \geq 0, x_2 \geq 0, x_1 + x_2 \leq 1), S_2 = \{(1, 2), R_2 = \{(0, 1)\}, D_2 = \emptyset\} \]

The convex-hull of \( P_1 \) (given by \( A \times B \)) and the vertex \( m = (1, 2) \) of \( P_2 \) is obtained (§ 3.3.1.1) by elimination of \( \lambda \) in \( \{(0, 0, 0), A_1 \times A_2, S_1 \times S_2, R_1 \times R_2, D_1 \times D_2\} \) minimizing \( \lambda \) in \( \{(0, 0, 0), A_1 \times A_2, S_1 \times S_2, R_1 \times R_2, D_1 \times D_2\} \), \( x_1 + x_2 + 2\lambda \leq 3 \) we get the approximation \( A' \times B' \) given by \( \{(x_1 \geq 0, x_2 \geq 0)\} \).

Incorporating the ray \( r = (1, 0) \) of \( P_1 \) in \( A' \times B' \) by elimination of \( \mu \) in \( \{(\mu, 0), A' \times A' \times B' \} \) that is \( \{(\mu, 0), x_1 + x_2 \leq 1, \emptyset, x_2 \geq 0\} \) we get the convex-hull of \( P_1 \) and \( P_2 \) given by \( \{(0, 0, 0), x_1 \geq 0, x_2 \leq x_1, x_1 \leq 1\) \).

End of example.

### 4.5. Loop junction nodes

**Each cycle in the program graph contains a loop junction node:**

![Loop junction node diagram]

The corresponding transformation \( P = \text{convex-hull}(P_1, P_2, \ldots, P_p) \) is defined by the widening operation \( \mathcal{V} \). Let \( Q_1(A_1, B_1, S_1, D_1) \) and \( Q_2(A_2, B_2, S_2, R_2, D_2) \) be two convex polyhedra. Then \( Q_1 \cup Q_2 \) is the convex polyhedron consisting in the linear restraints of \( Q_1 \) verified by every element of the frame \( (S_2, R_2, D_2) \) of \( Q_2 \).

**Example:**

\[ Q_1 = \{-x_1 + 2x_2 \leq 2, x_1 + 2x_2 \leq 6, x_2 \geq 0\}, s = \{\{(2, 0), (6, 0), (4, 1)\}), R = \emptyset, D = \emptyset\} \]

\[ Q_2 = \{-x_1 + 2x_2 \leq 2, x_1 + 2x_2 \leq 6, x_2 \geq 0\}, s = \{\{(2, 0), (10, 0), (6, 2)\}), R = \emptyset, D = \emptyset\} \]

\[ Q_1 \cup Q_2 = \{-x_1 + 2x_2 \leq 2, x_2 \geq 0\} \]

End of example.

In order to compute the frame of \( Q_1 \cup Q_2 \) it is necessary to convert from the linear restraint representation. Laney's method (§ 3.4) is known to be expensive. However when applied after a widening operation the cost remains reasonable because of the following arguments:

- In the widening \( Q_1 \cup Q_2 \) of \( Q_1 \) by \( Q_2 \) a certain number of vertices of \( Q_1 \) have been replaced by extreme rays. Hence the widening operation eliminates vertices, so that \( Q_1 \cup Q_2 \) can be assumed to have a small number of vertices. Now it is the discovery of vertices which is the most costly in Laney's method.

- A frame of \( Q_1 \) is known and \( Q_1 \) is included in \( Q_1 \cup Q_2 \). Therefore the initialization of the simplex method needs not to be used. Moreover since any restraint of \( Q_1 \cup Q_2 \) is a restraint of \( Q_1 \) it is highly probable that the frames of \( Q_1 \) and \( Q_1 \cup Q_2 \) have numerous common elements.

The correctness criterion of Cousot (1977) recalled at paragraph 2 is satisfied since \( Q_1 \leq Q_1 \cup Q_2 \), \( Q_2 \leq Q_1 \cup Q_2 \) and for every chain \( C_0 \leq C_1 \leq \ldots \leq C_n \) the chain \( S_0 = C_0, S_1 = S_0 \cup C_1, \ldots, S_n = \text{conv} \ldots C_n \) is an infinite strictly increasing chain since at each step \( n \) the number of constraints describing \( S_n \) is finite and less than or equal to the number of constraints describing \( S_{n-1} \).
The definition of the widening operation must be a balance between compelling the convergence of the program cycles and discovering as much information as possible about the program. Hence it is also not to perform widening operations at loop junction nodes before gathering the information along the program cycles containing that loop junction node. Also the definition of the widening which we have given is a tentative one. The experiments that have been carried out seem to corroborate our choice but further studies are necessary to give a definite conclusion.

6. GLOBAL ANALYSIS OF PROGRAMS.

We illustrate the global analysis of programs on a skeletal program which is simple enough to allow hand computations:

\[
\begin{align*}
(P_1) & \quad i := 2, j := 0; \\
(P_2) & \quad \text{if } \ldots \text{ then} \\
(P_3) & \quad i := i + 1; \\
(P_4) & \quad \text{else} \\
(P_5) & \quad j := i + 1; \\
(P_6) & \quad \text{go to } L; \\
\end{align*}
\]

The test involving a non-linear condition is not taken into account. Each assertion \( P_i \), \( i=0 \ldots 7 \) is initially the empty polyhedron \( \emptyset \) and the input assertion is propagated through the program graph:

\[
\begin{align*}
P_1^i & = \text{assign}(P_0^i, i := 2), j := 0) \\
&P_2^i = \text{convex-hull}(P_1^i, P_0^i) \\
&P_3^i = \text{assign}(P_1^i, i := i + 1) \\
&P_4^i = \text{assign}(P_1^i, j := i + 1) \\
&P_5^i = \text{convex-hull}(P_3^i, P_0^i) \\
\end{align*}
\]

The global analysis of programs will be

\[
\begin{align*}
P_7^i & = \text{assign}(P_6^i, i := i + 1) \\
&P_6^i = \text{convex-hull}(P_5^i, P_0^i) \\
&P_6^i = \text{assign}(P_5^i, j := j + 1) \\
&P_6^i = \text{assign}(P_5^i, i := i + 2) \\
&P_6^i = \text{convex-hull}(P_6^i, P_0^i) \\
\end{align*}
\]

when the loop body has been analyzed a widening operation takes place at the loop junction node \( L \):

\[
P_7^i = P_6^i \cup \text{convex-hull}(P_6^i, P_0^i)
\]

We have \( P_7^i = (2, 2, 2), i := 4 \) and

\[
\text{convex-hull}(P_6^i, P_0^i) = (2, 2, 2, i := 2, j := 0), \quad j := 0, \quad i := 2, j := 0,
\]

so that \( i := j + 1 \) which is the only constant of \( P_7^i \) not verified by every element of the frame of \( \text{convex-hull}(P_6^i, P_0^i) \) is eliminated by the widening operation.
Than \( p(w, h) \) is included in \( P' \) so that the program analysis has converged.

The final result shows up linear restraints among the variables of the program that never appear explicitly in the program text and often escape the notice of anyone studying this simple example:

\[
\begin{align*}
0 & : \text{no information} \\
1 & : i=2, j=0 \\
2 & : [i]+[2], j=0 \\
3 & : [i]+[2], j=0 \\
4 & : [i]+[2], j=2 \\
5 & : [i]+[2], j=1 \\
6 & : [i]+[2], i=1, j=0 \\
7 & : [i]+[2], j=1
\end{align*}
\]

6. EXAMPLE.

On the next example (HEAPSORT, Knuth[1973, p.148]) it is not possible to trace the details of the analysis so that we directly provide the results produced by our experimental implementation:

```
procedure HEAPSORT(Integer n, Value n;
real array [1..n] T)
begin integer L, R, I, J; real K;
L = (n div 2) + 1; R = n;
if (L > 2) then
  L = L - 1; (K := T[L]) R := R - 1;
else
  if (K > T[1]) then
    while (R > 2) do
      I = L; J = R; K = T[I];
    while (J > 1) do
      if (K > T[J]) then
        T[I] := T[J];
      od;
      T[I] := K;
  else
    while (L > 1) do
      I = L; J = R; K = T[I];
    while (J > 1) do
      if (K > T[J]) then
        T[I] := T[J];
      od;
      T[I] := K;
  end;  (end of the inner loop) I
end; od; (end of the outer loop)
```

The procedure is analyzed with the input specification N2.2 (see Knuth[1973, p.148]). This analysis does not take account of the statements involving operations on arrays, these statements such as \([K := T[L]]\) have been bracketed in the text of the procedure. The result of the analysis (taking about 20 seconds of C.P.U. time) is the following:

\[
\begin{align*}
1 & : N22 \\
7 & : N22 \Rightarrow C1 + 1, R, R2 \\
3 & : N22, N22 \Rightarrow N1 + 1, R, R2 \\
6 & : N22, N22 \Rightarrow N1 + 1, R, R2, L, L2 \\
8 & : R22, L2N1 + 1, R, N2, 2L + 2R + 1, 1N3, L21, RSN \\
10 & : R22, L2N1 + 1, R, N2, 2L + 2R + 1, 1N3, L21, RSN \\
11 & : R22, L2N1 + 1, R, N2, 2L + 2R + 1, 1N3, L21, RSN \\
12 & : R22, L2N1 + 1, R, N2, 2L + 2R + 1, 1N3, L21, RSN
\end{align*}
\]

7. NOTES ON THE EXPERIMENTAL IMPLEMENTATION.

We have produced an experimental implementation written in PASCAL on the CII-IRIS 80 computer. The length of the program is about 2500 lines.

The systems of equations and inequations have been represented for simplicity by real matrices and so this sometimes results in a loss of precision.

It seems very difficult to write the program so that this loss of precision is acceptable that is so that the relationships which have been found correspond to a domain including any value that each real variable can take during any execution of the analyzed program. However the main applications we have in mind (such as array bound checking) deal with integer variables. In this case the coefficients of the linear restraints are rational, which can be represented as fractions (p/q where p and q are integers). Then the operations which are performed on these coefficients (p, q, x) are much simpler but introduce no loss of precision.

We have noticed that programs involving numerical constants are better handled when these numerical constants are replaced by the declaration of a symbolic constant. It is often the case that the convergence of the analysis is faster although the systems of restraints are bigger.

It seems to be very difficult to evaluate the cost of the analysis of a program. The cost of the analysis does not only depend on the length (number of lines) of the program but mainly on the complexity of the program graph (number of loops, degree of loop combination, etc.). It seems that the cost of an analysis is almost linear in the length of the program but exponential in the number of variables involved in the analysis. From this point of view nested static scopes (such as ALGOL 68 blocks which authorizes very local declarations or better EUCLID with its import mechanism) is useful since for example the variables of an outer block \(b \) are analyzed independently of the variables of the inner blocks whereas the variable of the inner block can often be analyzed using only few global variables. In general it can be taken advantage of the scope rules of the usual languages.

We have deliberately taken the point of view not to take account of the legality restraints which must hold on the variables. For example if a program variable is used as an array index which do not take account of the fact that we should try to show that the value of this variable must be within the

\( j < R, 2L + 2R + 1, 3N \)

\( j = 15, \text{L1} \)

\( j = 16, \text{L2} \)

\( j = 21, \text{L2} \)

once the above invariant assertions have been discovered it is very easy using projections (3.3.1.1) to check statically that all array accesses are correct. Notice that some relationships among the variables of the procedure are not obvious and cannot be discovered by hand without deep understanding of the program.
array bounds. Taking account of such facts we
could propagate this information backward to the
loop junction nodes so that we would have a guide-
line for the widening operation. This would enable
us to combine the discovery and verification ap-
proaches.

Acknowledgements. We thank Rachid COUSOT for
helpful discussions on linear programming and
Mrs H.DIAZ for typing the manuscript.
