ABSTRACT

Explicit hybrid systems modelers like Simulink/Stateflow allow for programming both discrete- and continuous-time behaviors with complex interactions between them. A key issue in their compilation is the static detection of algebraic or causality loops. Such loops can cause simulations to deadlock and prevent the generation of statically scheduled code.

This paper addresses this issue for a hybrid modeling language that combines synchronous data-flow equations with Ordinary Differential Equations (ODEs). We introduce the operator \texttt{last}(x) for the left-limit of a signal x. This operator is used to break causality loops and permits a uniform treatment of discrete and continuous state variables. The semantics relies on non-standard analysis, defining an execution as a sequence of infinitesimally small steps. A signal is deemed causally correct when it can be computed sequentially and only changes infinitesimally outside of announced discrete events like zero-crossings. The causality analysis takes the form of a type system that expresses dependences between signals. In well-typed programs, signals are provably continuous during integration provided that imported external functions are continuous.

The effectiveness of this system is illustrated with several examples written in ZÈLUS, a Lustre-like synchronous language extended with hierarchical automata and ODEs.

1. CAUSALITY AND SCHEDULING

Tools for modeling hybrid systems [7] such as Modelica, LabVIEW, and Simulink/Stateflow are now rightly understood and studied as programming languages. Indeed, models are used not only for simulation, but also for test-case generation, formal verification and translation to embedded code. This explains the need for formal operational semantics for specifying their implementations and proving them correct [15, 9].

The underlying mathematical model is the synchronous parallel composition of stream equations, Ordinary Differential Equations (ODEs), hierarchical automata, and imperative features. While each of these features taken separately is precisely understood, real languages allow them to be combined in sophisticated ways. One major difficulty in such languages is the treatment of causality loops.

Causality or algebraic loops [20, 2-34] pose problems of well-definedness and compilation. They can lead to mathematically unsound models. They can prevent simulators from statically ensuring the existence of a fixed point, and compilers from generating statically scheduled code. The static detection of such loops, termed causality analysis, has been studied and implemented since the mid-1980s in synchronous data-flow language compilers [12, 13, 1]. The classical and simplest solution is to reject cycles (feed-back loops) which do not cross a unit delay. For instance, the Lustre-like equations:

\[
\begin{align*}
  x &= 0 \rightarrow \text{pre} \ y & &\text{and} & & y &= \text{if } c \text{ then } x + 1 \text{ else } x
\end{align*}
\]

define the two sequences \((x_n)_{n \in \mathbb{N}}\) and \((y_n)_{n \in \mathbb{N}}\) such that:

\[
\begin{align*}
  x(0) &= 0 & &y(n) &= \text{if } c(n) \text{ then } x(n) + 1 \text{ else } x(n) \\
  x(n) &= y(n - 1)
\end{align*}
\]

They are causally correct since the feedback loop for \(x\) contains a unit delay \texttt{pre} \(y\) (previous). Replacing \texttt{pre} \(y\) with \(y\) gives two non-causal equations. Causally correct equations can be statically scheduled to produce a sequential, loop-free function. Below is an excerpt of the C code generated by the Heptagon compiler [11] of Lustre:

\[
\begin{align*}
  \text{if (self->v_1)} \{ x = 0; \} \text{ else } \{ x = \text{self->v_2}; \} \\
  \text{if (c)} \{ y = x+1; \} \text{ else } \{ y = x; \} \\
  \text{self->v_2} = y; \text{ self->v_1} = \text{false};
\end{align*}
\]

4. The unit delay \(0 \rightarrow \text{pre}(\cdot)\), initialized to 0, is sometimes written as \(0 \text{by} \cdot (0 \text{ followed by} \cdot)\), or in Simulink: \(\frac{1}{2}\).
It computes current values of $x$ and $y$ from that of $c$. The internal memory of function \texttt{step} is in \texttt{self}, with \texttt{self->v_v1} initialized to true and set to false (to encode the \texttt{LUSTRE} operator $\rightarrow$) and \texttt{self->v_v2} storing the value of \texttt{pre y}.

**ODEs with resets:** Consider now the situation of a program defining continuous-time signals only, made of ODEs and equations. For example:

$$\text{der } y = z \text{ init } 4.0 \text{ and } z = 10.0 - 0.1 \cdot y,$$

defines signals $y$, $z$, and $k$, where for all $t \in \mathbb{R}^+$, $\frac{dy}{dt}(t) = z(t)$, $y(0) = 4$, $z(t) = 10 - 0.1 \cdot y(t)$, and $k(t) = y(t) + 1$. This program is causal simply because it is possible to generate a sequential function $\text{derivative}(y) = \text{let } z = 10 - 0.1 \cdot y \text{ in } z$ returning the current derivative of $y$ and initial value 4 for $y$ so that a numeric solver \cite{6} can compute a sequence of approximations $y(t_n)$ for increasing values of time $t_n \in \mathbb{R}^+$ and $n \in \mathbb{N}$. Thus, for continuous-time signals, integrators break algebraic loops just as delays do for discrete-time signals.

Can we reuse the simple justification we used for data-flow equations to justify that the above program is causal? Consider the value that $y$ would have if computed by an ideal solver taking infinitesimal steps of duration $\delta$ \cite{4}. Writing $\gamma y(n)$, $\gamma z(n)$ and $\gamma k(n)$ for the values of $y$, $z$ and $k$ at instant $n\delta$, with $n \in \mathbb{N}$ a non-standard integer, we have:

$$\gamma y(0) = 4,$$

$$\gamma z(n) = 10 - 0.1 \cdot \gamma y(n),$$

$$\gamma y(n+1) = \gamma y(n) + \gamma z(n) \cdot \delta$$

where $\gamma y(n)$ is defined sequentially from past values and $\gamma y(n)$ and $\gamma y(n+1)$ are infinitesimally close, for all $n \in \mathbb{N}$, yielding a unique solution for $y$, $z$ and $k$. The equations are thus causally correct.

Troubles arise when ODEs interact with discrete-time constructs, for example when a reset occurs at every occurrence of an event. E.g., the sawtooth signal $y: \mathbb{R}^+ \rightarrow \mathbb{R}^+$ such that $\frac{dy}{dt}(t) = 1$ and $y(t) = 0$ if $t \in \mathbb{N}$ can be defined by an ODE with reset,

$$\text{der } y = 1.0 \text{ init } 0.0 \text{ reset up}(y-1.0) \rightarrow 0.0$$

where $y$ is initialized with 0.0, has derivative 1.0, and is reset to 0.0 every time the zero-crossing $\text{up}(y-1.0)$ is true, that is, whenever $y - 1.0$ crosses 0.0 from negative to positive. Is this program causal? Again, consider the value $y_0$ would have were it calculated by an ideal solver taking infinitesimal steps of duration $\delta$. The value of $\gamma y(n)$ at instant $n\delta$, for all $n \in \mathbb{N}$ would be:

$$\gamma y(0) = 0,$$

$$\gamma y(n) = \gamma y(n-1) + \delta \text{ else } \gamma y(n),$$

$$\gamma y(n) = \gamma y(n-1) + \delta \text{ else } \gamma y(n-1)$$

This set of equations is clearly not causal: the value of $\gamma y(n)$ depends instantaneously on $\gamma z(n)$ which itself depends on $\gamma y(n)$. There are two ways to break this cycle: (a) consider that the effect of the zero-crossing is delayed by one cycle, that is, the test is made on $\gamma z(n-1)$ instead of on $\gamma z(n)$, or, (b) distinguish the zero-crossing of $\gamma y(n)$ from the value it would have had were there no reset, namely $\gamma y(n)$. Testing a zero-crossing of $\gamma y$ (instead of $y$).

$$\gamma c(n) = (\gamma y(n) - 1) \geq 0,$$

$\gamma y = \gamma e \text{ init } v_0$ stands for $y = \frac{1}{\delta}(\gamma y) \text{ initialized to } v_0 \text{ in } \text{SIMULINK}$. gives a program that is causal since $\gamma y(n)$ no longer depends instantaneously on itself. We propose writing this $\star$:

$$\text{der } y = 1.0 \text{ init } 0.0 \text{ reset up}(\text{last } y - 1.0) \rightarrow 0.0$$

where $\text{last}(y)$ stands for $\text{ly}$, that is, the \texttt{left-limit} of $y$. In non-standard semantics \cite{4}, it is infinitely close to the previous value of $y$, and written $\text{ly}(y) \approx y(n-1)$. When $y$ is defined by its derivative, $\text{last}(y)$ corresponds to the so-called ‘state port’ of the integrator block $\frac{1}{\delta}$ of \text{SIMULINK}, which is introduced expressly to break causality loops like the one above $\star$. \cite{2, 6-85}: \\[\text{The output of the state port is the same as the output of the block’s standard output port except for the following case. If the block is reset in the current time step, the output of the state port is the value that would have appeared at the block’s standard output if the block had not been reset.} \]

\text{SIMULINK} restricts the use of the state port. It is only defined for the integrator block and cannot be returned as a block output: it may only be referred to in the same context as its integrator block and used to break algebraic loops. The use of the state port reveals subtle bugs in the \text{SIMULINK} compiler. Consider the \text{SIMULINK} model shown in Figure 1a with the simulation results given by the tool for $x$ and $y$ in Figure 1b. The model contains two integrators. The one at left, named ‘Integrator0’ and producing $x$, integrates the constant 1. The one at right, named ‘Integrator1’ and producing $y$, integrates $x$: its state port is fed back through a bias block to reset both integrators, and through a gain of $-3$ to provide a new value for Integrator0. The new value for Integrator1 comes from the state port of Integrator0 multiplied by a gain of $-4$. In our syntax $\star$:

$$\text{der } x = 1.0 \text{ init } 0.0 \text{ reset } z \rightarrow -3.0 \text{ last } y$$

and $\text{der } y = x \text{ init } 0.0 \text{ reset } z \rightarrow -4.0 \text{ last } x$

In the non-standard interpretation of signals, the equations above are perfectly causal: the current values of $\gamma x(n)$ and $\gamma y(n)$ only depend on previous values, that is:

$$\gamma x(n) = \text{if } \gamma z(n) \text{ then } -3 \cdot \gamma y(n-1) \text{ else } \gamma x(n-1) + \partial \gamma y(n) = \text{if } \gamma z(n) \text{ then } -4 \cdot \gamma x(n-1) \text{ else } \gamma y(n-1) + \partial \gamma x(n-1)$$

Yet, can you guess the behavior of the model and explain why the trajectories computed by \text{SIMULINK} are wrong? Initially, both $x$ and $y$ are 0. At time $t = 2$, the state port of Integrator1 becomes equal to 2 triggering resets at each integrator as the output of block $u - 2.0$ crosses zero. The results show that Integrator0 is reset to $-6 (= 2 \cdot -3)$.

$\star$The $\star$’s link to http://zelus.di.ens.fr/hssc2014/.

$\gamma$The \texttt{SIMULINK} integrator block outputs both an integrated signal and a state port. We write $(x, lx) = \frac{1}{\delta}[(x_0, up(x, z)) \text{ for the integral of } x$, reset with value $x_0$ every time $z$ crosses zero from negative to positive, with output $x$ and state port $lx$. The example would thus be written:

$$(y, ly) = \frac{1}{\delta}(0.0, up(ly-1.0), 1.0).$$
Figure 1: A miscompiled Simulink model (R2009b) ▲
and that Integrator1 is reset to 24 (= −6 · −4). The latter result is surprising since, at this instant, the state port of Integrator0 should also be equal to 2, and we would thus expect Integrator1 to be reset to −8 (= 2 · −4)!

The SIMULINK implementation does not satisfy its documented behavior [19, 2-685]. Inspecting the C function which computes the current outputs,mdlOutputs in Figure 2, the code of the two integrators appears in an incorrectly scheduled sequence.\(^5\)

At the instant of the zero-crossing (conditions ssIsMajorTimeStep(S) and zcEvent are true), the state port of Integrator0 (stored in ssGetContStates(S)−→ Integrator0_CSTATE) is reset using the state port value of Integrator1. Thus, Integrator1 does not read the value of Integrator0’s state port (that is \(x(n − 1)\)) but rather the current value \(y(n)\) leading to an incorrect output. The SIMULINK model is not correctly compiled—it needs another variable to store the value of \(y(n − 1)\) just as a third variable is normally needed to swap the values of two others.

We argue that such a program should either be scheduled correctly or give rise to a warning or error message. Providing a means to statically detect and explain causality issues in a hybrid model is a key motivation of this paper.

Any loop in SIMULINK, whether of discrete- or continuous-time signals, can be broken by inserting the so-called memory block [19, 2-831].\(^9\) If \(x\) is a signal, mem(\(x\)) is a piecewise constant signal which refers to the value of \(x\) at the previous integration step (or major step). If those steps are taken at increasing instants \(t_i \in \mathbb{R}\), mem(\(x\))(\(t_0\)) = \(x_0\) where \(t_0 = 0\) and \(x_0\) is an explicitly defined initial value, mem(\(x\))(\(t_i\)) = \(x_{i−1}\) for \(i > 0\) and mem(\(x\))(\(t_i + \delta\)) = \(x_{i−1}\) for \(0 \leq \delta < t_{i+1} − t_i\). As integration is performed globally, mem(\(y\)) may cause strange behaviors as the previous value of a continuously changing signal \(x\) depends precisely on when the solver decides to stop! ▲ Writing mem(\(y\)) is thus unsafe in general [3,10]. There is nonetheless a situation where the use of the memory block is mandatory and still safe: The program only refers to the previous integration step during a discrete step. This situation is very common: it is typically that of a system with continuous modes \(M_1\) and \(M_2\) producing a signal \(x\), with each of them being started with the value computed previously by the solver, and mem(\(x\)) being used to pass a value from one mode to the other ▲. Instead of using the unsafe operator mem(\(x\)), we could better refer to the left limit of \(x\), and write it again last(\(x\)). Yet, the unrestricted use of this operation may cause a new kind of causality loop which has to be statically rejected. Consider the following equation activated on a continuous time base:

\[
y = −1.0 \cdot \text{last}(y) \text{ and init } y = 1.0
\]

which defines, for all \(n \in \mathbb{Z}\), the sequence \(y(n)\) such that:

\[
\text{last}(y(n)) = −y(n − 1) \quad y(0) = 1
\]

Indeed, this differs little from the equation \(y = −1.0 \cdot y\). Even though \(y(n)\) can be computed sequentially, its value does not increase infinitesimally at each step, that is, \(y\) is not left continuous even though no zero-crossing occurs. For any time \(t \in \mathbb{R}\), the set \(\{n | n \in \mathbb{Z}, n \neq 0\} = \text{dist}(y(n), y(n + 1)) = 1\}

Thus, the value of \(y(t)\) at any standard instant \(t \in \mathbb{R}\) is undefined.

Contribution and organization of the paper: This paper presents the causality problem for a core language

\(^5\)The same issue exists in release R2014a.

\(^9\)In contrast, the application of a unit delay \(\frac{1}{T}\) to a continuous-time signal is statically detected and results in a warning.

\(^{10}\)Quoting the SIMULINK manual (http://www.mathworks.com/help/simulink/slref/memory.html), “Avoid using the Memory block when both these conditions are true: - Your model uses the variable-step solver ode15s or ode113. - The input to the block changes during simulation.”
that combines Lustre-like stream equations, ODEs with reset and a basic control structure. The operator \texttt{last}(x) stands for the previous value of \(x\) in non-standard semantics and coincides with its left-limit when \(x\) is left-continuous.

This operation plays the role of a delay but is safer than and coincides with its left-limit when \(x\) stands for the previous value of a differential equations and control structures. Its syntax is:

\[ \text{(1)} \quad \text{let } \texttt{last}(x) \text{ in } \texttt{reset} \text{ and a basic control structure.} \]

The operator \texttt{reset} and a basic control structure. The operator \texttt{last}(x) stands for the previous value of \(x\) in non-standard semantics and coincides with its left-limit when \(x\) is left-continuous.

The paper is organized as follows. Section 2 introduces a core synchronous language with ODEs. Section 3 presents its semantics based on non-standard analysis. Section 4 presents a type system for causality and Section 5 a minimal one for the purpose of related work and we conclude in Section 7.

2. A SYNCHRONOUS LANGUAGE + ODES

We now introduce a kernel language. It is not intended to be a full language but a minimal one for the purpose of the present paper. It includes data-flow equations, ordinary differential equations and control structures. Its syntax is:

\[ \text{(2)} \quad \text{let } f \text{ where } \texttt{reset} \text{ and a basic control structure.} \]

A program is a sequence of definitions (\(d\)), that either bind the value of expression \(e\) to \(x\) (\texttt{let } \texttt{x} = e \text{ in } d) or define a function (\texttt{let } k \cdot f(p) = e \text{ where } E) In a function definition, \(k\) is the kind of the function \(f\), \(p\) denotes formal parameters, and the result is the value of an expression \(e\) which may contain variables defined in the auxiliary equations \(E\). There are three kinds of function: \(k = \lambda\) means that \(f\) is a combinational function (typically a function imported from the host language, e.g., addition); \(k = \mathbb{D}\) means that \(f\) is a sequential function that must be activated at discrete instants (typically a Lustre function with an internal discrete state); \(k = \mathbb{C}\) denotes a hybrid function that may contain ODEs and which must be activated continuously.

An expression \(e\) can be a variable (\(x\)), an immediate value \(v\), e.g., a boolean, integer or floating point value, the point-wise application of an imported function (\texttt{op}(e)) such as +,

* or \texttt{not}(\cdot), an initialized unit delay (\texttt{fby} \(e\)), the left-limit of a signal (\texttt{last}(x)), a function application (\(f(e)\)), a pair (\(e, e\)) or a rising zero-crossing detection (\texttt{up}(e)), which, in this language kernel, is the only basic construct to produce an event from a continuous-time signal \(e\). A pattern \(p\) is a tree structure of identifiers (\(x\)) and \(E\) is either an empty equation (\(\emptyset\)): an equality stating that a pattern equals the value of an expression at every instant \(x = e\); the initialization of a state variable \(x\) with a value \(e\) (\texttt{init} \(x = e\)) the value of a state variable \(x\) at the next instant \(\texttt{next} x = e\); or, the current value of the derivative of \(x\) (\(\texttt{der} x = e\)). An equation can also be the conjunction of two sets of equations \((E_1, E_2)\); the declaration that a variable \(x\) is defined within, and local to, a set of equations \((\texttt{local} \ x \ in \ E)\); a conditional that activates a branch according to the value of a boolean expression \(\texttt{if} e \texttt{then} E_1 \texttt{else} E_2\), and a variant that operates on an event expression \(\texttt{present} e \texttt{then} E_1 \texttt{else} E_2\).

Notational abbreviations:

(a) \texttt{if} \(e\) \texttt{then} \(E_1 \texttt{def} = \texttt{if} e \texttt{then} E_1 \texttt{else} ()\)

(b) \texttt{present} \(e\) \texttt{then} \(E_1 \texttt{def} = \texttt{present} e \texttt{then} E_1 \texttt{else} ()\)

(c) \texttt{der} \(x = e\) \texttt{init} \(e_0 \texttt{def} = \texttt{init} x = e_0 \texttt{and} \texttt{der} x = e\)

(d) \texttt{der} \(x = e\) \texttt{init} \(e_0 \texttt{reset} z \rightarrow e_1 \texttt{def} = \texttt{init} x = e_0 \texttt{and present} z \texttt{then} x = e_1 \texttt{else} \texttt{der} x = e\)

Equations \((E)\) must be in Static Single Assignment (SSA) form: every variable has a unique definition at every instant.

3. NON-STANDARD SEMANTICS

3.1 Semantics

Let \(\mathbb{R}\) and \(\mathbb{N}\) be the non-standard extensions of \(\mathbb{R}\) and \(\mathbb{N}\). \(\mathbb{N}\) is totally ordered and every set bounded from above (resp. below) has a unique maximal (resp. minimal) element. Let \(\partial \in \mathbb{R}\) be an infinitesimal, i.e., \(\partial > 0\), \(\partial = 0\). Let the global time base or base clock be the infinite set of instants:

\[ \mathbb{T}_\partial = \{ n : n = \partial n \mid n \in \mathbb{N}\} \]

\(\mathbb{T}_\partial\) inherits a total order from \(\mathbb{N}\); in addition, for each element of \(\mathbb{R}\), there exists an infinitesimally close element of \(\mathbb{T}_\partial\). Whenever possible we leave \(\partial\) implicit and write \(T\) instead of \(\mathbb{T}_\partial\). Let \(T = \{ n : n \in \mathbb{N}\} \subseteq \mathbb{T}\). \(T(\mathbb{i})\) stands for \(\mathbb{i}\), the \(i\)-th element of \(T\). In the sequel, we only consider subsets of the time base \(T\) obtained by sampling a time base on a boolean condition or a zero-crossing event. Any element of a time base will thus be of the form \(k + \partial \mathbb{N}\) where \(k \in \mathbb{N}\). If \(T \subseteq \mathbb{T}\), we write \(\mathbb{T}(t)\) for the immediate predecessor of \(t\) in \(T\) and \(\mathbb{T}^*(t)\) for the immediate successor of \(t\) in \(T\). For an instant \(t\), we write its immediate predecessor and successor as, respectively, \(t^-\) and \(t^+\), rather than as \(\mathbb{T}(t)\) and \(\mathbb{T}^*(t)\). For \(t \in T \subseteq \mathbb{T}\), neither \(t^-\) nor \(t^+\) necessarily belong to \(T\). \(\mathbb{min}(T)\) is the minimal element of \(T\) and \(t \leq t'\) means that \(t\) is a predecessor of \(t'\) in \(T\).

**Definition 1 (Signals):** Let \(V_1 = V \oplus \{ \bot \} \) where \(V\) is a set. \(S(V) = \mathbb{T} \rightarrow V_1\) is the set of signals. A signal \(x : T \rightarrow V_1\) is a total function \(f\) from a time base \(T \subseteq \mathbb{T}\) to \(V_1\). Moreover, for all \(t \in T\), \(x(t) = \bot\). If \(T\) is a time base, \(x(T(n))\) and \(x(t)\) are the value of \(x\) at instant \(t\) where
$n \in \mathbb{N}$ is the $n$-th element of $T$. The clock of a signal $x$ is $\text{clock}(x) = \{ t \in T \mid x(t) \neq \bot \}$.

**Sampling:** Let $\text{bool} = \{ \text{false}, \text{true} \}$ and $x : T \rightarrow \text{bool}$. The sampling of $T$ according to $x$, written $T$ on $x$, is the subset of instants defined by:

$$ T \cap x = \{ t \mid (t \in T) \land x(t) = \text{true} \} $$

Note that as $T$ on $x \subset T$, it is also totally ordered. The zero-crossing of $x : T \rightarrow \mathbb{R}_+$ is $\text{up}(x) : T \rightarrow \text{bool}$. To emphasize that $\text{up}(x)$ is defined only for $t \in T$, we write its value at time $t$ as $\text{up}(x)(T)(t)$. For $t \notin T$, $\text{up}(x)(T)(t) = \bot$.

In the definition below is the total order on $\mathbb{R}_+$.

$$ \text{up}(x)(T)(t_0) = \text{false} \quad \text{where} \quad t_0 = \min(T) $$

$$ \text{up}(x)(T)(t) = \exists n \in \mathbb{N}, n \geq 1. \quad \land (x(t-n\delta) < 0) \land (x(t-(n-1)\delta) = 0) \land \ldots $$

$$ \land (x(t-\delta) = 0) \land (x(t) > 0) $$

where $t \in T$

The above definition means that a zero-crossing on $x$ occurs when $x$ goes from a strictly negative to a strictly positive value, possibly with intermediate values equal to 0.

Let $V$ be a set of values closed under product and sum. $V$ is its non-standard extension such that $\{ V_1 \times V_2 \} = V_1 \times V_2$. $V^\# = V$ for any finite set $V$. $V^\# \sqcup = V + \{ \bot \}$ with $\bot$ as the minimum element. Let $L = \{ x_1, \ldots, x_n \}$ be a set of local variables and $\mathcal{L}_G$ be a set of global variables. An environment associates values to names. A local environment $\rho$ and a global environment $G$ map names to signals and signal functions:

$$ \rho : L \rightarrow S(V) \quad G : L_G \rightarrow (S(V) \rightarrow S(V)) $$

**Operations on environments:** Consider $\rho_1$ and $\rho_2$.

- $(\rho_1 + \rho_2)(x)(t) = \rho_1(x)(t)$ if $\rho_2(x)(t) = \bot$, $\rho_2(x)(t)$ if $\rho_1(x)(t) = \bot$, and $\rho_2(x)(t)$ otherwise.

- $\rho = \text{merge}(T)(s)(\rho_1)$ is the merge of two environments according to a signal $s \in S(\text{bool})$. The value of a signal $x$ at instant $t \in T$ is the one given by $\rho_1$ if $s(t)$ is true and that of $\rho_2$ otherwise. Nonetheless, in case $x$ is not defined in $\rho_1$ (respectively $\rho_2$), it implicitly keeps its previous value, that is $\rho_1(\text{clock}(x)(t))$. This corresponds to adding an equation $x = \text{last}(x)$ when no equation is given in one branch of a conditional.

For all $x$ and $t \in T$, $\rho(x)(t) = \rho_1(x)(t)$ if $s(t) = \text{true}$ and $x \in \text{Dom}(\rho_1)$; $\rho(x)(t) = \rho_2(x)(t)$ if $s(t) = \text{false}$ and $x \notin \text{Dom}(\rho_1); \rho(x)(t) = \rho(x)(\text{clock}(x)(t))$ if $s(t) = \text{true}$ and $x \notin \text{Dom}(\rho_1)$. $\rho(x)(t) = \rho_2(x)(t)$ if $s(t) = \text{false}$ and $x \in \text{Dom}(\rho_2)$; finally, $\rho(x)(t) = \rho(x)(\text{clock}(x)(t))$ otherwise.

**Expressions:** Expressions are interpreted as signals and node definitions as functions from signals to signals. For expressions, we define $[e_1]_G^*(T)(t)$ to give at every instant $t \in T$ both the value of $e$ and a Boolean value true if $e$ raises a zero-crossing event. The definition is given in Figure 3.

Let us explain the definition. The value of expression $e$ is considered undefined outside of $T$. The current value of an instantaneous constant $v$ is $v$ and no zero-crossing event is raised. The current value of $x$ is the one stored in the environment $\rho(x)$ and no event is raised. The semantics of $\uparrow[e_1]_G^*(T)(t)$ is $\uparrow[\text{false}]$ if $t \notin T$;

$\uparrow[e_1]_G^*(T)(t)$ is $v$, false;

$\uparrow[x]_G^*(T)(t)$ is $\rho(x)(t)$, false;

$\uparrow[\text{op}(v)]_G^*(T)(t)$ is $\text{let } v, z = \uparrow[e_1]_G^*(T)(t) \text{ in } \text{op}(v), z$;

$\uparrow[(e_1, e_2)]_G^*(T)(t)$ is $\text{let } v_1, z_1 = \uparrow[e_1]_G^*(T)(t) \text{ in } \text{let } v_2, z_2 = \uparrow[e_2]_G^*(T)(t) \text{ in } (v_1, v_2), (z_1 \lor z_2)$;

$\uparrow[e_1 \text{ if } e_2]_G^*(T)(t)$ is $\uparrow[e_1]_G^*(T)(t)$ if $t = \min(T)$;

$\uparrow[e_1 \text{ if } e_2]_G^*(T)(t)$ is $\uparrow[e_2]_G^*(T)(t)$; otherwise $\rho(x)(\uparrow[\text{clock}(x)(t)]_G^*(T)(t))$.

$\uparrow[\text{fby}(e_1, e_2)]_G^*(T)(t)$ is $\text{let } s(t), z(t) = \uparrow[e_1]_G^*(T)(t) \text{ in } \text{let } v', z' = G(f)(s(t)) \text{ in } v', z(t) \lor v'$;

$\uparrow[\text{up}(e)]_G^*(T)(t)$ is $\text{let } s(t), z(t) = \uparrow[e_1]_G^*(T)(t) \text{ in } \text{let } v' = \text{up}(s)(T)(t) \text{ in } v', z(t) \lor v'$.

$\text{Function definitions:}$ Function definition is our final concern: we must show the existence of fixed points in the sense of Kahn process network semantics based on Scott domains. The prefix order on signals $S(V)$ indexed by $\exists \subseteq \mathbb{R}_+$ is defined as: signal $x$ is a prefix of signal $y$, written $x \leq_{S(V)} y$, if $x$ is a prefix of $y$ and $x \neq \bot$.
\[ \begin{aligned}
\&\forall t \in T.s(t), z(t) = \uparrow [e]_{G}^{c}(T)(t) \\
\&\forall t \in T.s(t), z(t) = \uparrow [e]_{G}^{c}(T)(t)
\end{aligned} \]
where \(\forall t \in T.s(t), z(t) = \uparrow [e]_{G}^{c}(T)(t)\)
and \(\forall t \in T.s(t), z(t) = \uparrow [e]_{G}^{c}(T)(t)\)
and \(\forall t \in T. (v, z = \uparrow [e]_{G}^{c}(T)(t)) \land (s(t^{*}) = v)\)
and \(\forall t \in T. (v, z = \uparrow [e]_{G}^{c}(T)(t)) \land (s(t^{*}) = s(t) + \partial \times v)\)

Figure 4: The non-standard semantics of equations

\(x(t) \neq y(t)\) implies \(x(t') = \perp\) for all \(t' \) such that \(t < t'\). The minimum element is the undefined signal \(\perp_{S(V)}\) for which
\(\forall t \in T, \perp_{S(V)}(t) = \perp\). When possible, we write \(\perp\) for \(\perp_{S(V)}\)
and \(x \leq y\) for \(x \leq y\). The symbol \(\bigvee\) denotes a supremum
in the prefix order. A function \(f : S(V) \rightarrow S(V)\) is continuous if
\(\bigvee_{i} f(x_{i}) = f(\bigvee_{i} x_{i})\) for every increasing chain of signals, where
increasing refers to the prefix order. If \(f\) is continuous, then equation \(x = f(x)\) has a least solution
denoted by \(\text{fix}(f)\), and equal to \(\bigvee_{i} f^{(i)}(\perp)\). We name such
continuity on the prefix order Kahn continuity [14].

The prefix order is lifted to environments so that \(\rho \leq \rho'\)
iff for all \(x \in \text{Dom}(\rho) \cup \text{Dom}(\rho')\), \(\rho(x) \leq \rho'(x)\). It is lifted
to pairs such that \((x, y) \leq (x', y')\) iff \(x \leq x'\) and \(y \leq y'\).

**Property 1 (Kahn Continuity).** Let \([s/p]\) be an environment, \(G\) a
global environment of Kahn-continuous functions and \(T\) a clock. The function:
\(F : (L \rightarrow S(V)) \times S(\text{bool}) \rightarrow (L \rightarrow S(V)) \times S(\text{bool})\)
such that:

\[ F(\rho, z) = \text{let } \rho' = \rho' \text{, } z' = \uparrow [E]_{G}^{c+|p|}(T) \text{ in } \rho', z \text{ or } z' \]

is Kahn continuous, that is, for any sequence \((\rho_{i}, z_{i})\) \(i \geq 0:\)

\[ F(\bigvee_{i} (\rho_{i}, z_{i})) = \bigvee_{i} F(\rho_{i}, z_{i}) \]

As a consequence, an equation \((\rho, z) = F(\rho, z)\) admits a
least fixed point \(\text{fix}(F) = \bigvee_{i} F^{(i)}(\perp, \perp)\).

The declaration of \(\forall t \in T. (v, z = \uparrow [e]_{G}^{c}(T)(t))\) defines
a Kahn-continuous function \(f\) such that:

\[ \forall t \in T. (v, z = \uparrow [e]_{G}^{c}(T)(t)) \]

Yet, Kahn-continuity of \(f\) does not mean that the function
computes anything interesting. In particular, the semantics
gives a meaning to functions that become ‘stuck’, like:\`
\begin{verbatim}
let hybrid f(x) = y where rec y = y + x
\end{verbatim}\`

The semantics of \(f\) is \(\uparrow f(x) = \perp\) since the minimal solution
of equation \(y = y + x\) is \(\perp\). The purpose of the causality
analysis is to statically reject this kind of program.

### 3.2 Standardization

We now relate the non-standard semantics to the usual
super-dense semantics of hybrid systems. Following [18],
the execution of a hybrid system alternates between integration
steps and discrete steps. Signals are now interpreted as
total functions from the time index \(S = \mathbb{R} \times \mathbb{N}\) to \(V\).
This time index is called super-dense time [18, 15]. It is
ordered lexically, \((t, n) < (t', n')\) iff \(t < t'\) or \(t = t'\)
and \(n < n'\). Moreover, for any \((t, n)\) and \((t', n')\) where \(n \leq n'\),
if \(x(t, n') \neq \perp\) then \(x(t, n) \neq \perp\).

A **timeline** for a signal \(x\) is a function \(N_{x} : \mathbb{R}_{+} \rightarrow \mathbb{N}\).
\(N_{x}(t)\) is the number of instances of \(x\) that occur at a real
date \(t\) and such timelines thus specify a subset of super-dense
time \(\mathbb{S}_{N_{x}} = \{(t, n) \in \mathbb{S} \mid n \leq N_{x}(t)\}\). In particular,
if \(N_{x}\) is always 0, then \(\mathbb{S}_{N_{x}}\) is isomorphic to \(\mathbb{R}_{+}\). For \(t \in \mathbb{R}\)
and \(T \subseteq \mathbb{R}_{+}\), define:

\[ \text{set}(T)(t) \triangleq \{ t' \in T \mid t' \approx t \land t' \in \mathbb{R} \} \subseteq T \]

that is, the set of all instances infinitely close to \(t\). \(T\) is totally
ordered and hence so is \(\text{set}(T)(t)\). Let \(x : T \rightarrow V\).

We now proceed to the definition of the **timeline** \(N_{x}\) of \(x\)
and the **standardization** of \(x\), written

\[ \text{std}(x) : \mathbb{R} \times \mathbb{N} \rightarrow V_{+}, \]

such that \(\text{std}(x)(t, n) = \perp\) for \(n > N_{x}(t)\).

Let \(T^{*} \triangleq \text{set}(T)(t)\) and consider

\[ \text{std}(x(T^{*})) \triangleq \{ \text{std}(x(t')) \mid t' \in T^{*}\}. \]

\(^{1}\)The keyword **hybrid** stands for \(k = C\) and **node** for \(k = \mathbb{D}\).
Our approach differs slightly from [15], where the value of a

... takes a single argument

... by asserting the value

... of type

... that 

... invariants, e.g.,

... zero-crossings, that is, signals must evolve continuously dur-

... the value

... is continuous during integration. The second one states

... semantics and causality issues.

(i) If \( Z = \{t_0, \ldots, t_m\} \) is finite, timeline \( N(x)(t) = m \) and the standard value of signal \( x \) at time \( t \) is:

\[
\forall n \in \{0, \ldots, m\}, \text{st}(x)(t, n) = \text{st}(x(t_{n+1}))
\]

(ii) If \( Z \) is infinite (it may even lack a minimum element), let

\[
N(x)(t) = \bot \quad \text{and} \quad \forall n, \text{st}(x)(t, n) = \text{st}(x(t_{n+1}))
\]

which corresponds to a Zeno behavior.

Our approach differs slightly from [15], where the value of a signal is frozen for \( n > N(t) \). We decide instead to set it to the value \( \bot \). Each approach has its merits. For ours, parts of signals that do not experience jumps are simply indexed by \((t, 0)\) which we identify with \( t \). In turn, we squander the undefined value \( \bot \) which is usually devoted to Scott-Kahn semantics and causality issues.

3.3 Key properties

We now define two main properties that reasonable programs should satisfy. The first one states that discontinuities do not occur outside of zero-crossing events, that is, signals are continuous during integration. The second one states that the semantics should not depend on the choice of the infinitesimal. These two invariants are sufficient conditions to ensure that a standardization exists.

Invariant 1 (Zero-crossings). An expression \( e \) evaluated under \( G \), \( \rho \) and a base time \( T \) has no discontinuity outside of zero-crossing events. Formally, define \( s(t), z(t) = \left[ \begin{array}{c} \text{st}(x)(T)(t) \\ \text{st}(x)(t, n) \end{array} \right] \) such that \( \forall t, t' \in T \) such that \( t \leq t' \):

\[
t \approx t' \Rightarrow (\exists t'' \in T, t \leq t'' \leq t' \land z(t'')) \lor s(t') \approx s(t')
\]

This invariant states that all discontinuities are aligned on zero-crossings, that is, signals must evolve continuously during integration. Discrete changes must be announced to the solver using the construct \( \mathsf{up}(\cdot) \). Not all programs satisfy the invariant, e.g.,

let hybrid \( f() = y \) where \( \text{rec } y = \text{last } y + 1 \) and init \( y = 0 \)

\( f \) takes a single argument \( 0 \) of type unit and returns a value \( y \). Writing \( y(n) \) for the value of \( y \) at instant \( n\Delta \) with \( n \in \mathbb{N} \), we get \( y(0) = 0 \) and \( y(n) = (y(n - 1) + 1 \). Yet, \( y(n) \neq y(n - 1) \) while no zero-crossing is registered for any instant \( n \in \mathbb{N} \). This program will be statically rejected by using the type system developed in the next section.

Invariant 2 (Independence from \( \partial \)). The semantics of \( e \) evaluated under \( G \), \( \rho \) and a base time \( T \) is independent of the infinitesimal time step. Formally, define \( s(t) = \text{fst}(\left[ \begin{array}{c} \text{st}(x)(T)(t) \\ \text{st}(x)(t, n) \end{array} \right]) \) and \( s'(t) = \text{fst}(\left[ \begin{array}{c} \text{st}(x)(T_{n-1})(t) \end{array} \right]) \), then:

\[
\forall t \in \mathbb{R}, n \in \mathbb{N}, \text{st}(s)(t, n) = \text{st}(s')(t, n)
\]

When satisfied, this invariant ensures that properties and values on non-standard time carry over to standard time and values.

4. A LUSTRE-LIKE CAUSALITY

Programs are statically typed. We adopt, for our language, the type system presented in [3]. Well-typed programs may still exhibit causality issues, that is, the definition of a signal at instant \( t \) may instantaneously depend on itself. A classical causality analysis is to reject loops which do not cross a delay. This ensures that outputs can be computed sequentially from current inputs and an internal state. This simple solution is used in the academic LUSTRE compiler [12], LUCID SYNCHRONIZE [22] and SCADe.12 We propose generalizing it to a language mixing time equations, ODEs and their synchronous composition. The causality analysis essentially amounts to checking that every loop is broken either by a unit delay or an integrator.

The analysis gives sufficient conditions for invariants 1 and 2. We adopt the convention quoted below [3, 4]. A signal is termed \( \text{discrete} \) if it only changes on a \( \text{discrete clock} \).

A clock is termed \( \text{discrete} \) if it has been declared

so or if it is the result of a zero-crossing or a sub-sampling of a discrete clock. Otherwise, it is termed \( \text{continuous} \).

A discrete change on \( x \) at instant \( t \) in \( T \) means that \( x(t) \neq x(t) \) or \( x(t) \neq x(t)^* \). Said differently, all discontinuities have to be announced using the programming construct \( \mathsf{up}(\cdot) \). Two classes of approaches exist to formalize causality analyses. In the first, causality is defined as an abstract preorder relation on signal names. The causality preorder evolves dynamically at each reaction. A program is causally correct if its associated causality preorder is provably a partial order at every reaction. In the second class, causality is defined as the tagging of each event by a ‘stamp’ taken from some preordered set. The considered program is causally correct if its set of stamps can be partially ordered—similarly to Lamport vector clocks. Previous works [1, 4] belong to the first class whereas this paper belongs to the second.

Our analysis associates a type to every expression and function via two predicates: \( \text{(typ-exp)} \) states that, under constraints \( C \), global environment \( G \), local environment \( H \), and kind \( k \in \{A, B, C\} \), an expression \( e \) has type \( ct \); \( \text{(typ-env)} \) states that under constraints \( C \), global environment \( G \), local environment \( H \), and kind \( k \), the equation \( E \) produces the type environment \( H' \).

\[
\begin{align*}
\text{(typ-exp)} & : C \mid G, H \vdash_k e : ct \\
\text{(typ-env)} & : C \mid G, H \vdash_k E : H'
\end{align*}
\]

The type language is

\[
\begin{align*}
\sigma & ::= \forall \alpha_1, \ldots, \alpha_n : C, \text{ct}\ k \ ct \\
ct & ::= \text{ct} \times \text{ct} \mid \alpha \\
k & ::= D | C | A
\end{align*}
\]

where \( \sigma \) defines type schemes, \( \alpha_1, \ldots, \alpha_n \) are type variables and \( C \) is a set of constraints. A type is either a pair \( \text{ct} \times \text{ct} \) or a type variable \( \alpha \). The typing rules for causality are defined with respect to an environment of causality types. \( G \) is a global environment mapping each function name to a type scheme \( (\sigma) \). \( H \) is a local environment mapping each variable \( x \) to its type \( \text{ct} \):

\[
G ::= [\sigma_1/f_1, \ldots, \sigma_k/f_k] \quad H ::= [\text{ct}_1/x_1, \ldots, \text{ct}_n/x_n]
\]

12http://www.esterel-technologies.com/scade
\[ \frac{(\text{Taut})}{C + \alpha_1 < \alpha_2 \vdash \alpha_1 < \alpha_2} \quad \frac{(\text{Trans})}{C \vdash \alpha_1 < \alpha' \quad C \vdash \alpha' < \alpha_2} \subseteq C \vdash \alpha_1 < \alpha_2 \]

\[ \frac{(\text{Pair})}{C \vdash \alpha_1 < \alpha' \quad C \vdash \alpha' < \alpha_2} \subseteq C \vdash \alpha_1 < \alpha_2 \]

\[ \frac{(\text{Env})}{\forall i \in \{1, \ldots, n\}, C \vdash \alpha_i < \alpha'} \subseteq C \vdash [x_1 : \alpha_1; \ldots; x_n : \alpha_n] \]

The typing relation is defined in Figure 6:

Rule (Var). A variable \( x \) inherits the declared type \( \alpha \).

Rule (Const). A constant \( e \) has any causality type.

Rule (App). An application \( f(e) \) has type \( \alpha \) if \( f \) has function type \( \alpha_1 \rightarrow \alpha_2 \) from the instantiation of a type scheme giving a new set of constraints \( C \), and \( e \) has type \( \alpha_1 \).

Rule (Last). \( \text{last}(x) \) is the previous value of \( x \). In this system, we only allow \( \text{last}(x) \) to appear during a discrete step (of kind D).

Rule (Eq). An equation \( e = e' \) defines an environment \([\alpha/\alpha']\) if \( \alpha \) and \( \alpha' \) are of type \( \alpha \).

Rule (Sub). If \( e \) is of type \( \alpha \) and \( \beta < \alpha \) then \( e \) can also be given the type \( \beta \).

Rule (Def). An integrator has a similar role as a unit delay: it breaks dependencies during integration. If \( \beta : \alpha \rightarrow \gamma \) then any use of \( x \) does not depend instantaneously on the computation of \( e \) and can thus be given the type \( \beta \).

Rules (Present) and (Step). The present statement returns an environment \( H \). The first handler is activated during discrete steps and the second one has kind \( C \). The rules for conditionals are the same except that the handlers and condition must all be of kind \( k \).

Rule (Local). The declaration of a local variable \( x \) is valid if \( E \) gives an equation for \( x \) which is itself causal.

Rule (Def). For a function \( f \) with parameter \( p \) and result \( e \), the body \( E \) is first typed under an environment \( H \) and constraints \( C \). The resulting environment \( H' \) must be strictly less than \( H \). This forbids any direct use of variables in \( H \) when typing \( E \).

We can now illustrate the system on several examples.

Example: The following program is a classic synchronous (thus discrete-time) program written in the concrete syntax of ZÉLUS. Calling the forward Euler integrator integr below, the function heat is valid since integr does not depend instantaneously on \( \text{gain} - \text{temp} \cdot \text{step} \) is a global constant.

\[
\begin{align*}
\text{let node integr}(x_i, x') &= x \quad \text{where rec } x = x_i \text{ fby } (x + x' \cdot \text{step}) \\
\text{let node heat}(\text{temp0}, \text{gain}) &= \text{temp where rec } \text{temp} = \text{integr}(\text{temp0}, \text{gain})
\end{align*}
\]

The causality signatures are:

\[
\begin{align*}
\text{val integr} & : ('a < 'b). 'a -> 'b -C-> 'a \\
\text{val heat} & : ('a < 'b). 'a -> 'b -C-> 'a
\end{align*}
\]

The signature for integr states that the output depends instantaneously on its first argument but not the second one. The following program is statically rejected:

\[
\text{let cycle}() = (x, y) \quad \text{where rec } y = x + 1 \text{ and } x = y + 2
\]

Indeed, taken \( x : \alpha_1 \) and \( y : \alpha_2 \), the first equation is correct if both \( C + \alpha_1 < \alpha_2 \) and \( C + \alpha_2 < \alpha_1 \). This means that \( C \) must contain \( \{ \alpha_1 < \alpha_2, \alpha_2 < \alpha_1 \} \) which is cyclic. This following two are correct, der playing the role of a delay:

\[
\begin{align*}
\text{let cycle}_1() &= (x, y) \quad \text{where rec } z = x + 1 \\
\text{let cycle}_2() &= (x, y) \quad \text{where rec } y = x + 1
\end{align*}
\]
In the present system, let hybrid loop() = y where rec y = f(y)
loop
let hybrid g(x) = o where a discrete context. Hence, the following program is rejected.

\[ \alpha \text{ typed, we would need to be able to state an equation} \]
\[ \forall \alpha, \alpha \in \{ \mathbb{G}, \mathbb{H} \} \]
\[ \text{and} \ x = \text{last} x + y \text{ and init } x = 0.0 \]

An extension is to allow \text{last}(x) \text{ to appear in a continuous context provided } x \text{ is a continuous state variable, i.e., it is defined by an equation } \text{der} x = e. \text{ Indeed, during integration } \text{last}(x) \text{ and } x \text{ are infinitely close to each other } (\frac{1}{2}(x(n - 1)) \approx \frac{1}{2}(x(n))). \text{ The ZÉLUS compiler implements this minor extension.}

\section{5. THE MAIN THEOREM}
We can now state the main result of this paper: The semantics of well-typed programs satisfies Invariants 1 and 2. This theorem requires assumptions on primitive operators and imported functions, as the following example shows.

A Nonsmooth Model A: It comprises several modules (written in ZÉLUS syntax). The first two are an integrator and a time base with a parameterized initial value \( t_0 \):

\[ \text{let hybrid integrator}(y_0, x) = y \text{ where} \]
\[ \text{rec init y} = y_0 \text{ and} \text{der } y = x \]
\[ \text{let hybrid time}(t_0) = \text{integrator}(t_0, 1.0) \]

Then a function producing a quasi-Dirac (Dirac with a width strictly greater than 0). It yields a function \text{dirac}(d,t) such that \( \int_{-\infty}^{\infty} \text{dirac}(d,t)dt = 1 \) for every constant \( d > 0 \):

\[ \text{let dirac}(d, t) = (d / \pi) \ast d / (d + d * t * t) \]

Our goal is to produce, using a hybrid program, an infinitesimal value for \( d \), so that \text{dirac}(d,t) standardizes as a Dirac measure centered on \( t = 0 \). This can be achieved by integrating a pulse of magnitude 1, but of infinitesimal width. Such a pulse can be produced using a variable that is reset twice by the successive occurrences, separated by a \( \delta \), of two zero-crossings:
let hybrid doublecrossing(t) = (x + 1.0) / 2.0 where 
rec init x = -1.0 
and present up(t) then do next x = 1.0 done else 
present up(x) then do next x = -1.0 done else do der x = 0.0 done 
let hybrid infinitesimal(t1, t) = 
integrator(0.0, doublecrossing(t1))

The first zero-crossing in doublecrossing occurs when \( t \) crosses zero and causes an immediate reset of \( x \) from \(-1\) to \(+1\), this in turn triggers an immediate zero-crossing on \( x \) and a reset of \( x \) back to \(-1\). The input of the integrator is thus one for \( \theta \)-step; the output of the integrator, initially \( 0 \), becomes \( \theta \) at time \( t_1 + \theta \).

The main program is the following, where \( t_0 < t_1 < t_2 \):

let hybrid nonsmooth(t0, t1, t2) = x where 
rect = time(t0) and d = infinitesimal(t - t1) and 
x = integrator(0.0, dirac(d, (t - t2)))

What is the point of this example? It is causally correct and yet its standardization has a discontinuity at \( t_2 \) though no zero-crossing occurs. This is because \( \text{dirac} \) standardizes to a Dirac mass.

**Discussion:** In the previous example, the problem arises with the function \( \text{dirac} \), that is not defined when \( t = 0 \) and \( d = 0 \). However, it is defined everywhere when \( d \neq 0 \). In particular, it is defined for \( d = 0 \). The solution seems clear: if a standard function \( f(x) \) of a real variable \( x \) is such that \( f(x_0) = 1 \), then the semantics must enforce \( f(x) = 1 \) for any \( x \approx x_0 \). Applying this to the function \( d \to d \in \mathbb{R} \) where \( t = 0 \) is fixed gives \( \frac{x}{\sqrt{\epsilon}} = \frac{x}{1} \). This is formalized through the assumptions on operators and functions given below.

Given \( x, y \in \mathbb{R} \), relation \( x 
\approx y \) holds iff \( \text{st}(x - y) = 0 \). Recall that function \( f : \mathbb{R} \to \mathbb{R} \) is **microcontinuous** if for all \( x, y \in \mathbb{R} \), \( x 
\approx y \) implies \( f(x) 
\approx f(y) \). Recall that the microcontinuity of \( f \) implies the uniform continuity of \( \text{st}(f) : \mathbb{R} \to \mathbb{R} \) [17]. Denote \( [t_0, t_1] = \{ t \in \mathbb{T} | t_0 \leq t \leq t_1 \} \), with \( t_0, t_1 \in \mathbb{T} \) finite.

**Assumption 1.** Operators \( \text{op}(\cdot) \) of kind \( \mathcal{C} \) are standard and satisfy the following definedness, finiteness and continuity properties:

\[
\begin{align*}
\text{op}(\bot) & = \bot \\
\forall \epsilon, \text{op}(v) \neq \bot & \text{ implies } \text{op}(u) \text{ finite} \\
\forall \epsilon, v, u \approx v & \text{ and } \text{op}(u) \neq \text{op}(v) \text{ implies } \text{op}(u) = \bot
\end{align*}
\]

**Assumption 2.** Environment \( G \) is assumed to satisfy the following assumption, for all external functions \( f \) of kind \( \mathcal{C} \): for any bounded interval \( K = [t_1, t_2] \), for any input \( u \) that is defined, finite and microcontinuous on \( K \), if function \( G(f)(u) \) is defined and produces no zero-crossing in \( K \), then it is assumed to be finite and microcontinuous on \( K \):

\[
\begin{align*}
\forall t \in K, & \ f^*(\text{st}(G(f)(u))(t)) \neq \bot & \text{ and } \text{snd}(G(f)(u))(t)) = \emptyset \\
\forall t \in K, & \ f^*(\text{st}(G(f)(u))(t)) \neq \bot \implies \text{st}(G(f)(u))(t)) = \bot
\end{align*}
\]

**Lemma 1.** Assume that Assumptions 1 and 2 hold. For any activation clock \( T \subseteq \mathbb{T} \), for any bounded interval \( K = [t_1, t_2] \), for any environment \( \rho \) that is defined, finite and microcontinuous on \( K \), if expression \( e \) of kind \( \mathcal{A} \) or \( \mathcal{C} \), is defined and produces no zero-crossing on \( K \), then it is finite and microcontinuous on \( K \): 

\[
\begin{align*}
\forall t \in K, & \ f^*(\text{st}(\text{op}(G(e))(T))(t)) \neq \bot & \text{ and } \text{snd}(\text{st}(\text{op}(G(e))(T))(t)) = \emptyset \\
\forall t \in K, & \ f^*(\text{st}(\text{op}(G(e))(T))(t)) \neq \bot \implies \text{st}(\text{op}(G(e))(T))(t)) = \bot
\end{align*}
\]

**Corollary 1.** Assume that Assumptions 1 and 2 hold, and that \( e \) is a causally correct expression of kind \( \mathcal{A} \) or \( \mathcal{C} \). For any activation clock \( T \subseteq \mathbb{T} \), for any bounded interval \( K = [t_1, t_2] \), for any environment \( \rho \) that is defined, finite and microcontinuous on \( K \), if the least fixed point of the operator \( \rho' \) is defined and raises no zero-crossing on \( K \), then \( \rho' \) is microcontinuous on \( K \).

6. DISCUSSION AND RELATED WORK

The present work continues that of Benveniste et al. [4], by exploiting non-standard semantics to define causality in a hybrid program. The proposed analysis gives a sufficient condition for the program to be statically scheduled.
The present work is related to Ptolemy [10] and the use of synchronous language concepts to define the semantics of hybrid modelers [16]. We follow the same path, replacing super-dense semantics by non-standard semantics that we found more helpful to explain causality constraints and generalize solutions adopted in synchronous compilers. The presented material is implemented in ZÉLUS, a synchronous language extended with ODEs [6]. It is more single-minded than Ptolemy but ZÉLUS programs are turned into sequential code whereas Ptolemy only provides an interpreter.

Causality has been extensively studied for the synchronous languages SIGNAL [1] and ESTEREL [5]. Instead of imposing that every feedback loop crosses a delay, constructive causality checks that the corresponding circuit is constructive. A circuit is constructive if its outputs stabilize in bounded time when inputs are fed with a constant input. In the present work, we adapted the simpler causality of LUSTRE and LUCID SYNCHRONE based on a precedence relation in order to focus on specific issues raised when mixing discrete and continuous-time signals. Schneider et al. [2] have considered the causality problem for a hybrid extension of Quartz, a variant of ESTEREL, with ODEs. But, they did not address issues due to the interaction of discrete and continuous behaviors.

Regarding tools like SIMULINK, we think that the synchronous interpretation of signals where time advances by infinitesimal steps can be helpful to define causality constraints and safe interactions between mixed signals.

7. CONCLUSION

Causality in system modelers is a sufficient condition for ensuring that a hybrid system can be implemented: general fix-point equations may have solutions or not, but the subset of causally correct systems can definitely be computed sequentially using off-the-shelf solvers. The notion of causality we propose is that of a synchronous language extended with ODEs [6]. It is more single-minded than Ptolemy but ZÉLUS programs are turned into sequential code whereas Ptolemy only provides an interpreter.
